1976 TABLES OF CONTENTS

Following is a condensed version of the tables of contents for the January through December issues of the *American Journal of Psychiatry*. These cumulative contents pages will allow readers to locate quickly the issues in which specific articles were published. All regular articles, topical papers, special section papers, brief communications, editorials, and obituaries are listed by title and author. Individual letters to the editor and book reviews can be located by consulting the author and subject indices.

P 24,346

January 1976

1 Overview: Maintenance Therapy in Psychiatry: II. Affective Disorders
John M. Davis

14 An Investigation of the Postpsychotic Depressive Syndrome
Thomas H. McGlashan and William T. Carpenter, Jr.

20 Behavioral Characteristics of Children with Chronic Nonspecific Diarrhea
Esther H. Wender, Frederick B. Palmer, John J. Herbst, and Paul H. Wender

26 Studies of Superobesity: II. Psychiatric Appraisal of Jejuno-Ileal Bypass Surgery
Pietro Castelnuovo-Tedesco and Douglas Schiebel

32 Maintenance Antipsychotic Therapy: Is the Cure Worse Than the Disease?
George Gardos and Jonathan O. Cole

37 The Natural History of "Chipping"
Norman E. Zinberg and Richard C. Jacobson

41 Countertransference: A Neglected Subject in Clinical Supervision
Marcia Kraft Goin and Frank Kline

45 Treatment Plans for Mental Health Care
David J. Knesper and Derek Miller

51 Peer Review and PSRO: An Update
Frank W. Sullivan

TOPICAL PAPERS: Some Aspects of Community Psychiatry

56 Community Mental Health Center Legislation: Flight of the Phoenix
Frank M. Ochberg

61 Correlates of Patient Attendance in an Inner-City Mental Health Clinic
Thomas J. Craig and Carol L. Huffine

65 Mental Health Services and the Elderly: Needs and Options
Gene D. Cohen

69 Community Alternatives to Institutional Care
Lucy D. Ozarin

73 A Note on Some Recent Studies of Released Mental Hospital Patients in the Community
Leona L. Bachrach

EDITORIAL

76 Editing Circa 1976
F.J.B.

BRIEF COMMUNICATIONS

80 Antiparkinsonian Agents and Fluphenazine Decanoate
Scott Idzorek

82 Thioridazine and Sexual Dysfunction
Joel Kotin, Donald E. Wilbert, David Verburg, and Simon M. Soldinger

85 Methodology and Personality in Briquet's Syndrome: A Reappraisal
Michael J. Kaminsky and Phillip R. Slavney

89 Editorial Practices of Psychiatric and Related Journals: Implications for Women
Elissa P. Benedek

93 Routine Skull Films in Hospitalized Psychiatric Patients
John F. Delaney

95 Psychiatry and Folk Healing: A Dichotomy?
Pedro Ruiz and John Langrod

98 We Help Each Other: Primary Prevention for the Widowed
William F. McCourt, Ruth D. Barnett, Jean Brennen, and Alvin Becker

IN MEMORIAM

101 Benjamin Harris Balser, 1905–1975
Robert S. Mumford

102 **LETTERS TO THE EDITOR**

107 Correction: Hans R. Huessy: "Putting Our House in Order" (ltr to ed), (132:1083, 1975)

108 **BOOK REVIEWS**

February 1976

125 Overview: Ethical Issues in Contemporary Psychiatry
Fritz Redlich and Richard F. Mollica

137 Current Trends in the Training of Family Therapists
Edward W. Beal

142 Crime and Violence Among Mental Patients
Arthur Zitrin, Anne S. Hardesty, Eugene I. Burdock, and Ann K. Drossman
150 Cluster Analysis Profiles of Suicide Attempters
Ari Kiev
154 The Behavior Therapies: Therapeutic Breakthrough or Latest Fad?
Arthur K. Shapiro
160 Psychiatric Aspects of Dwarfism
James S. Brust, Charles V. Ford, and David L. Rimoin
165 Viral Encephalopathy Mimicking Functional Psychosis
Lawrence G. Wilson

SPECIAL SECTION: Current Concepts of Schizophrenia

171 Introduction
Richard Jed Wyatt
172 Current Diagnostic Concepts in Schizophrenia
William T. Carpenter, Jr.
177 The Interaction of Social Class and Other Factors in the Etiology of Schizophrenia
Melvin L. Kohn
181 The Family and Schizophrenia
David Reiss
185 Estimating the Genetic Contribution to Schizophrenia
Steven W. Matthysse and Kenneth K. Kidd
192 Serum Creatine Phosphokinase in Schizophrenia
Herbert Y. Meltzer
197 The Dopamine Hypothesis of Schizophrenia: Focus on the Dopamine Receptor
Solomon H. Snyder
203 The Psychedelic Model of Schizophrenia: The Case of *N,N*-Dimethyltryptamine
J. Christian Gillin, Jonathan Kaplan, Richard Stillman, and Richard Jed Wyatt
208 Recent Developments in the Drug Treatment of Schizophrenia
John M. Davis

EDITORIAL

215 An Opportunity to Stimulate Self-Evaluation and Learning
Sidney L. Werkman

BRIEF COMMUNICATIONS

217 The Educational Objectives of a Psychiatric Residency Program
Joel Yager and Robert O. Pasnau
220 The Effect of Marijuana on Carbohydrate Metabolism
M. Alan Permutt, Donald W. Goodwin, Robert Schwin, and Shirley Y. Hill
222 Joint Admission as a Treatment Modality for Problem Drinkers: A Case Report
Thomas J. Paolino, Jr., and Barbara S. McCrady
225 Chronic Hashish Use and Mental Disorder
Costas Stefanis, Aris Liakos, John Boulougouris, Max Fink, and Alfred M. Freedman
228 Mania and Bromism: A Case Report and a Look to the Future
A. Joseph Sayed
230 Breaking Into the Prison: Conducting a Medical Research Project
Jeffrey S. Rubin

233 LETTERS TO THE EDITOR

236 Correction: Beatrix A. Hamburg, Helena C. Kraemer, and William Jahnke: "A Hierarchy of Drug Use in Adolescence: Behavioral and Attitudinal Correlates of Substantial Drug Use" (132:1155–1163, 1975)

237 BOOK REVIEWS

OFFICIAL ACTIONS

LIFT THE MASK OF SCHIZOPHRENIC WITHDRAWAL

'STELAZINE' PROVIDES EFFECTIVE CONTROL OF HALLUCINATIONS, DELUSIONS, ANXIETY AND OTHER PSYCHOTIC SYMPTOMS.

BECAUSE IT APPEARS TO HAVE AN ACTIVATING EFFECT, 'STELAZINE' IS ESPECIALLY USEFUL IN WITHDRAWN, APATHETIC OR DETACHED PATIENTS.

- CONTROLS PSYCHOTIC SYMPTOMS
- SELDOM CAUSES EXCESSIVE SEDATION
- CONVENIENT B.I.D. DOSAGE

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F Co.) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only) 10 mg./ml.

HELPS WITHDRAWN PATIENTS BECOME MORE RESPONSIVE.

EXCITING NEW TITLES FROM HALSTED PRESS

A DIVISION OF JOHN WILEY & SONS, INC.

THE DEVELOPMENT OF TRADITIONAL PSYCHOPATHOLOGY

By **M. D. Altschule,** Harvard University.
ISBN 0-470-02521-2 1975 300 pp. $18.50
(A Hemisphere publication)

A sourcebook going back to the original texts, including many previously untranslated landmark writings. Includes sections on the unconscious mind, unconscious psychologic manifestations of sexuality, psychotic thinking, the ego, multiple personalities, primary mechanisms and symptoms, affective disorders, depression, witchcraft, hypochondria, thought and nervous disorders.

DEPRESSION: Behavioral, Biochemical, Diagnostic and Treatment Concepts

Edited by **D. M. Gallant,** Tulane University, and **G. M. Simpson,** Rockland State Hospital.
ISBN 0-470-01375-3 1975 352 pp. $25.00 (tentative)
(A Hemisphere publication)

International authorities present up-to-date information on the epidemiology and classification of depression. Experimental data, animal models, and theories of biochemical factors are included. Methodological problems in evaluating antidepressants and depression in children are two important topics.

ON THE DEVELOPMENT OF A TOKEN ECONOMY MENTAL HOSPITAL TREATMENT PROGRAM

By **Raymond A. Ulmer,** Drew Postgraduate Medical Center.
ISBN 0-470-01393-1 1975 300 pp. $17.95
(A Hemisphere publication)

Describes the theory and humane practice of token economy in complete detail. Shows how a token economy works effectively, and ineffectively, and describes the selection, pre-service, and in-service training for involved disciplines. Specifies ways of assessing patients, examines current criticisms of behavior therapy, and considers administrative problems.

IN SEARCH OF IDENTITY

By **A. C. Paranjpe,** Simon Fraser University.
ISBN 0-470-65856-8 1975 300 pp. $12.50

Deals with the development of personality during adolescence and early adulthood, using intensive longitudinal studies of a small number of individuals. Erikson's theory of identity formation is used as a conceptual framework. A major test of cross-cultural application of a North American theory of personality development.

THEORETICAL PRINCIPLES OF PSYCHOSOMATIC MEDICINE

By **I. T. Kurtsin** (trans. by N. Kaner).
ISBN 0-470-51100-1 1975 300 pp. $35.00

A survey of world literature and experimental data on the physiological mechanisms of corticovisceral disturbances arising from psychogenic trauma, or overexertion, of the higher nervous function, and on the development of mental (emotional) stress.

ADVANCES IN SLEEP RESEARCH, VOLUME 2

Edited by **Elliot D. Weitzman,** Montefiore Hospital.
ISBN 0-470-93301-1 1975 350 pp. $20.00 (tentative)
(A Hemisphere publication)

Deals with both the basic and clinical aspects of the field in a multidisciplinary manner. Examines such topics as sleep patterns in infants and a sleep study of acute psychotic states due to alcohol and meprobamate addiction.

CURRENT DEVELOPMENTS IN PSYCHOPHARMACOLOGY, VOLUME 2

Edited by **W. B. Essman,** Queens College of CUNY, and **L. Valzelli,** Mario Negri Institute for Pharmacological Research.
ISBN 0-470-24568-9 1975 350 pp. $20.00
(A Hemisphere publication)

Includes papers in flurothyl, the action of central nervous system stimulant drugs, and depression and brain dopamine.

A75 Index to Advertisers

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in duplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit two copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

Communications about a manuscript, by letter or telephone (202-232-7878), should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; in the case of other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, which is a copyrighted publication, the legal ownership of all parts of the paper, including any illustrations, passes from the author to the *Journal*. If an individual or organization wishes to reprint material published in the *Journal*, written permission must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Wash., D.C. 20009; there will usually be a charge for granting this permission.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not reflect the official attitude or position of the American Psychiatric Association or of the *Journal's* Editorial Board.

SPECIFICATIONS FOR MANUSCRIPTS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond (or other opaque) paper. All parts of the manuscript (including case reports, footnotes, references, etc.) should be double-spaced, with generous margins. Subheads should be inserted at reasonable intervals to aid in comprehension and to break the typographical monotony of lengthy texts. Abbreviations not easily recognized by the average reader should be explained.

Length. As a general rule the manuscript of a regular article should not exceed 10–12 typed pages, unless a special arrangement has been made with the Editor; Brief Communications should not exceed eight typed pages. Letters to the Editor should not exceed 500 words unless a special arrangement has been made with the Editor.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the co-author who has been designated to handle the galley proofs and reprint requests. The number of authors should preferably not exceed four, with other collaborators being acknowledged in a footnote.

Precis. A brief precis is included at the beginning of each article: 60–100 words for regular articles, 40–60 words for Brief Communications. The author may prepare the precis himself or ask that the *Journal* staff prepare it, in which case the author may make any necessary changes on the galley proofs.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

References. References should be typed double-spaced on a separate sheet of paper, to be attached at the end of the manuscript. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below for books and journal articles; chapters in books will be treated as journal articles with regard to capitalization. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Titles and headings of any tables and figures should be sufficiently clear that the meaning of the data is understandable without reference to the text. See recent issues of the *Journal* for the general requirements of style.

Each table should be typed on a separate sheet, attached at the end of the manuscript. The data should be arranged so that columns of like material read down, not across.

A complete set of figures, preferably in the form of glossy prints, should accompany each of the two copies of the manuscript. Most figures will be reduced to about 3¼ inches in width, the column width of the *Journal*; all elements of a figure should be prepared to withstand this reduction. Graphs should be finished drawings not requiring further artwork. Authors are urged to engage the services of a professional in the preparation of figures. Authors may be required to meet the costs of any further artwork that must be done in the editorial office.

AUTHORS' CORRECTIONS

Galley proofs will be sent to the first-named author for corrections after the paper has been scheduled for publication; prompt return (preferably within 48 hours of receipt) is necessary to ensure publication in the assigned month. If an author expects to be away from his office for a long period of time after he has received the acceptance letter, he should inform the *Journal* office or arrange with a colleague to read the proofs. Authors are urged to keep changes on galleys to a minimum.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be attached to the galley proofs submitted to authors for correction. Reprints are usually mailed to authors about a month after publication of the article. Requests from others to order reprints should be directed to the Editor; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

Released from symptoms of psychotic depression...

Productive again.

By helping to reduce the frequency and intensity of psychotic symptoms, Navane (thiothixene) often permits resumption of more normal, more productive living.

The antipsychotic effectiveness of Navane—with relatively little drowsiness—helps patients remain more active, more alert, better able to meet the ordinary demands of life.

Cardiovascular side effects such as hypotension and nonspecific EKG changes are relatively rare with Navane (thiothixene). Extrapyramidal symptoms have been reported, but are usually controlled by reduction in dosage and/or administration of antiparkinson drugs.

Once you've controlled acute psychosis or psychotic depression, some patients can be maintained on a simple once-a-day dose. This once-a-day regimen can reduce the risk of missed doses with no loss of efficacy.

Navane®

(thiothixene) (thiothixene hydrochloride)

Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg/Concentrate 5 mg/ml

Once-a-day–to help control symptoms of psychosis

For prescribing information, including adverse reactions and contraindications please see following page of this advertisement.

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Actions. Navane is a psychotropic agent of the thioxanthene series. Navane possesses certain chemical and pharmacological similarities to the piperazine phenothiazines and differences from the aliphatic group of phenothiazines. Navane's mode of action has not been clearly established.

Indications. Navane is effective in the management of manifestations of psychotic disorders.

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy* – Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children–The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration – As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane. Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudoparkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leucocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate–In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor elevating action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg, of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals

In clinically significant depression

TABLETS, 5 mg and 10 mg

Vivactil®*

(Protriptyline HCl | MSD)

*** When you want an antidepressant that is characteristically nonsedating for the patient under close medical supervision (Symptoms such as anxiety or agitation may be aggravated.)**

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information please see following page.

In clinically significant depression

TABLETS, 5 mg and 10 mg

Vivactil®

(Protriptyline HCl | MSD)

Contraindications: Known hypersensitivity; acute recovery phase following myocardial infarction. Should not be given concomitantly with an MAOI; hyperpyretic crises, severe convulsions, and deaths have occurred in patients receiving tricyclic antidepressant and MAOI drugs simultaneously. When it is desired to substitute protriptyline HCl for an MAOI, a minimum of 14 days should be allowed to elapse after the latter is discontinued. Protriptyline HCl should then be initiated cautiously with gradual increase in dosage until optimum response is achieved.

Warnings: May block the antihypertensive effect of guanethidine or similarly acting compounds. May impair mental and/or physical abilities required for the performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Should be used with caution in patients with a history of seizures and, because of its autonomic activity, in patients with a tendency to urinary retention or increased intraocular tension.

Tachycardia and postural hypotension may occur more frequently than with other antidepressant drugs. Should be used with caution in elderly patients and patients with cardiovascular disorders; such patients should be observed closely because of the tendency of the drug to produce tachycardia, hypotension, arrhythmias, and prolongation of the conduction time. Myocardial infarction and stroke have occurred with drugs of this class. On rare occasions, hyperthyroid patients or those receiving thyroid medication may develop arrhythmias when this drug is given.

Usage in Children: Not recommended for use in children because safety and effectiveness in the pediatric age group have not been established.

Usage in Pregnancy: Safe use in pregnancy and lactation has not been established; therefore, use in pregnant women, nursing mothers, or women who may become pregnant requires that possible benefits be weighed against possible hazards to mother and child.

Precautions: When protriptyline HCl is used to treat the depressive component of schizophrenia, psychotic symptoms may be aggravated; likewise, in manic-depressive psychosis, depressed patients may experience a shift toward the manic phase; paranoid delusions, with or without associated hostility, may be exaggerated. In any of these circumstances, it may be advisable to reduce the dose of protriptyline HCl or to use a major tranquilizing drug concurrently. Symptoms, such as anxiety or agitation, may be aggravated in overactive or agitated patients.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. May enhance response to alcohol and effects of barbiturates and other CNS depressants. Possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have access to large quantities of the drug. Concurrent administration with electroshock therapy may increase hazards of therapy; such treatment should be limited to patients for whom it is essential. Discontinue drug several days before elective surgery, if possible. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions which have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when protriptyline HCl is administered. Protriptyline HCl is more likely to aggravate agitation and anxiety and produce cardiovascular reactions such as tachycardia and hypotension.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions, anxiety, restlessness, agitation; insomnia, panic, and nightmares; hypomania; exacerbation of psychosis.

Neurological: numbness, tingling, and paresthesias of extremities; incoordination, ataxia, tremors, peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns, tinnitus.

Anticholinergic: dry mouth and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of the urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (general, or of face and tongue), drug fever.

Hematologic: bone marrow depression; agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia.

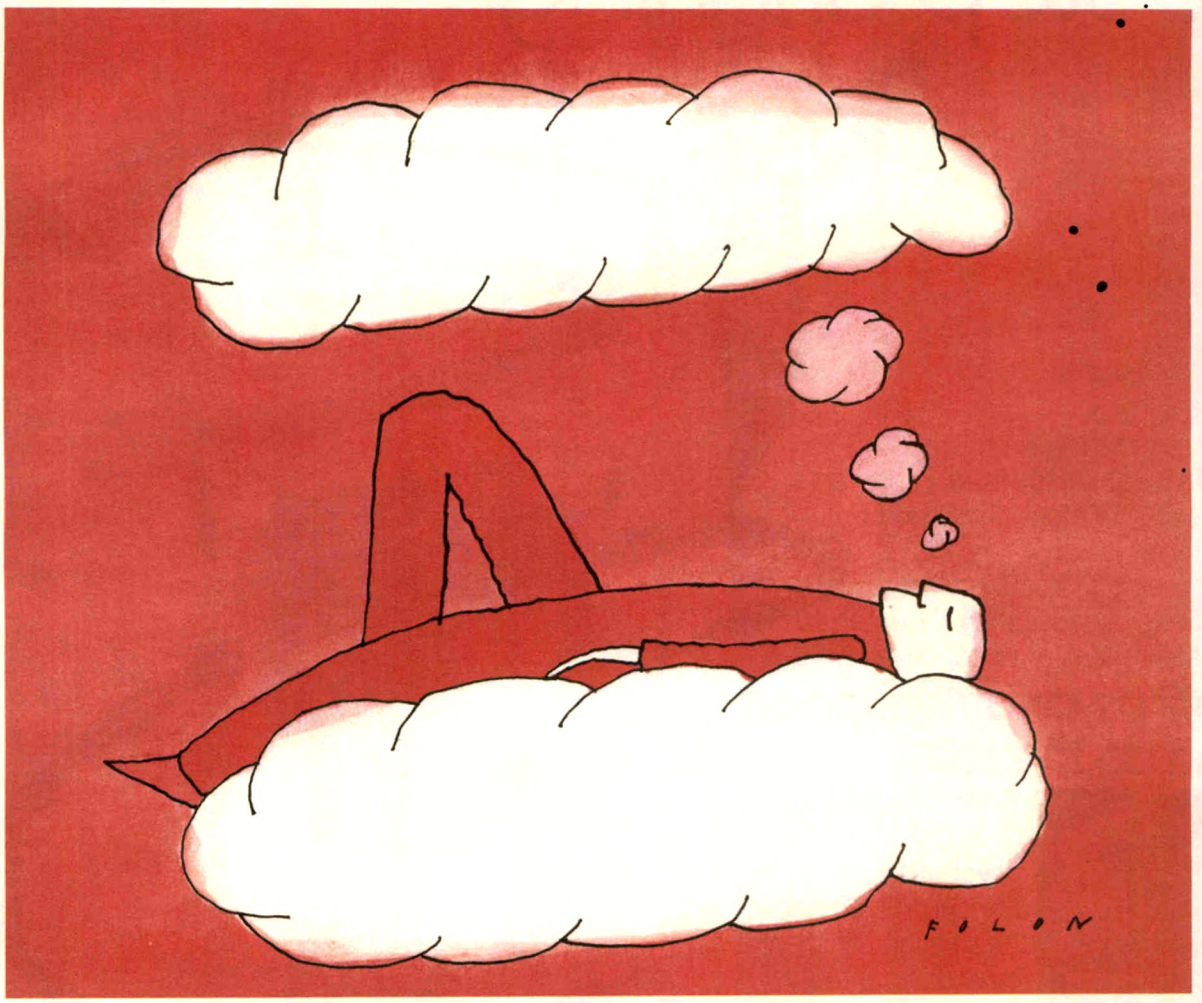
Gastrointestinal: nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of other tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.



How Supplied: Tablets, containing 5 mg and 10 mg protriptyline HCl each, in single-unit packages of 100 and bottles of 100 and 1000.

ANTABUSE: "Social security" for the alcoholic who wants to stop drinking...

The temptation is resisted, ANTABUSE (disulfiram) represents the security alcoholics need in any situation. They are better able to abstain from drinking because they know the consequences of taking "even one."

until psychiatric support can do the rest

Undoubtedly it will take considerable time for psychotherapy to help the chronic alcoholic. As a psychiatrist, you have undoubtedly selected the patients who are best motivated to stay with ANTABUSE while you attempt to deal with the underlying emotional problems. And, of course, you know the importance of reminding patients of the serious consequences of drinking while on ANTABUSE.

Once sober, and well into treatment, the alcoholic, at your discretion, can participate in a total treatment program which makes use of various supportive resources in the community. In the meantime, ANTABUSE can help the chronic alcoholic abstain from drinking.

BRIEF SUMMARY
(For full prescribing information, see package circular.)

ANTABUSE® (disulfiram) in Alcoholism

INDICATION: ANTABUSE is an aid in the management of selected chronic alcoholic patients who want to remain in a state of enforced sobriety so that supportive and psychotherapeutic treatment may be applied to best advantage. (Used alone, without proper motivation and without supportive therapy, ANTABUSE is not a cure for alcoholism, and it is unlikely that it will have more than a brief effect on the drinking pattern of the chronic alcoholic.)

CONTRAINDICATIONS: Patients who are receiving or have recently received metronidazole, paraldehyde, alcohol, or alcohol-containing preparations, *e.g.* cough syrups, tonics, and the like, should not be given ANTABUSE.

ANTABUSE is contraindicated in the presence of severe myocardial disease or coronary occlusion, psychoses, or hypersensitivity.

WARNINGS: ANTABUSE should never be administered to a patient when he is in a state of alcohol intoxication or without his full knowledge.

The physician should instruct relatives accordingly.

The patient must be fully informed of the ANTABUSE-alcohol reaction. He must be strongly cautioned against surreptitious drinking while taking the drug, and he must be fully aware of possible consequences. He should be warned to avoid alcohol in disguised form, *i.e.* in sauces, vinegars, cough mixtures, and even aftershave lotions and back rubs. He should also be warned that reactions may occur with alcohol up to 14 days after ingesting ANTABUSE.

THE ANTABUSE-ALCOHOL REACTION: ANTABUSE plus alcohol, even small amounts, produces flushing, throbbing in head and neck, throbbing headache, respiratory difficulty, nausea, copious vomiting, sweating, thirst, chest pain, palpitation, dyspnea, hyperventilation, tachycardia, hypotension, syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion. In severe reactions there may be respiratory depression, cardiovascular collapse, arrhythmias, myocardial infarction, acute congestive heart failure, unconsciousness, convulsions, and death.

The intensity of the reaction varies with each individual, but is generally proportional to the amounts of ANTABUSE (disulfiram) and alcohol ingested. Mild reactions may occur in the sensitive individual when the blood alcohol concentration is increased to as little as 5 to 10 mg. per 100 cc. Symptoms are fully developed at 50 mg. per 100 cc., and unconsciousness usually results when the blood alcohol level reaches 125 to 150 mg.

The duration of the reaction varies from 30 to 60 minutes to several hours in the more severe cases, or as long as there is alcohol in the blood.

DRUG INTERACTIONS: Disulfiram appears to decrease the rate at which certain drugs are metabolized and so may increase the blood levels and the possibility of clinical toxicity of drugs given concomitantly.

Disulfiram should be used with caution in those patients receiving diphenylhydantoin and its congeners, since toxic levels of these antiepileptic agents have been reported during concomitant disulfiram therapy.

It may be necessary to adjust the dosage of oral anticoagulants upon beginning or stopping disulfiram, since disulfiram may prolong prothrombin time.

Patients taking isoniazid when disulfiram is given should be observed for the appearance of unsteady gait or marked changes in mental status and the disulfiram discontinued if such signs appear.

CONCOMITANT CONDITIONS: Because of the possibility of an accidental ANTABUSE-alcohol reaction, ANTABUSE (disulfiram) should be used with extreme caution in patients with any of the following conditions: diabetes mellitus, hypothyroidism, epilepsy, cerebral damage, chronic and acute nephritis, hepatic cirrhosis or insufficiency.

USAGE IN PREGNANCY: The safe use of this drug in pregnancy has not been established. Therefore, ANTABUSE (disulfiram) should be used during pregnancy only when, in the judgment of the physician, the probable benefits outweigh the possible risks.

PRECAUTIONS: It is suggested that every patient under treatment carry an Identification Card, stating that he is receiving ANTABUSE and describing the symptoms most likely to occur as a result of the ANTABUSE-alcohol reaction. In addition, this card should indicate the physician or institution to be contacted in emergency. (Cards may be obtained from Ayerst Laboratories upon request.)

Alcoholism may accompany or be followed by dependence on narcotics or sedatives. Barbiturates have been administered concurrently with ANTABUSE (disulfiram) without untoward effects, but the possibility of initiating a new abuse should be considered.

Base line and follow-up transaminase tests (10-14 days) are suggested to detect any hepatic dysfunction that may result with ANTABUSE therapy. In addition, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

ADVERSE REACTIONS: (See Contraindications, Warnings, and Precautions.)

Occasional skin eruptions are, as a rule, readily controlled by concomitant administration of an antihistaminic drug.

In a small number of patients, a transient mild drowsiness, fatigability, impotence, headache, acneform eruptions, allergic dermatitis, or a metallic or garlic-like aftertaste may be experienced during the first two weeks of therapy. These complaints usually disappear spontaneously with the continuation of therapy or with reduced dosage.

Psychotic reactions have been noted, attributable in most cases to high dosage, combined toxicity (with metronidazole or isoniazid), or to the unmasking of underlying psychoses in patients stressed by the withdrawal of alcohol.

There have been reports of polyneuritis and peripheral neuritis, and rare instances of optic neuritis. One case of cholestatic hepatitis has been reported, but its relationship to ANTABUSE has not been unequivocally established.

DOSAGE AND ADMINISTRATION: ANTABUSE (disulfiram) should never be administered until the patient has abstained from alcohol for at least 12 hours.

INITIAL DOSAGE SCHEDULE: In the first phase of treatment, a maximum of 500 mg. daily is given in a single dose for one to two weeks. Although usually taken in the morning, ANTABUSE may be taken on retiring by patients who experience a sedative effect. Alternatively, to minimize, or eliminate, the sedative effect, dosage may be adjusted downward.

MAINTENANCE REGIMEN: The average maintenance dose is 250 mg. daily (range, 125 to 500 mg.); it should not exceed 500 mg. daily.

NOTE: Occasional patients, while seemingly on adequate maintenance doses of ANTABUSE (disulfiram), report that they are able to drink alcoholic beverages with impunity and without any symptomatology. All appearances to the contrary, such patients must be presumed to be disposing of their tablets in some manner without actually taking them. Until such patients have been observed reliably taking their daily ANTABUSE tablets (preferably crushed and well mixed with liquid), it cannot be concluded that ANTABUSE is ineffective.

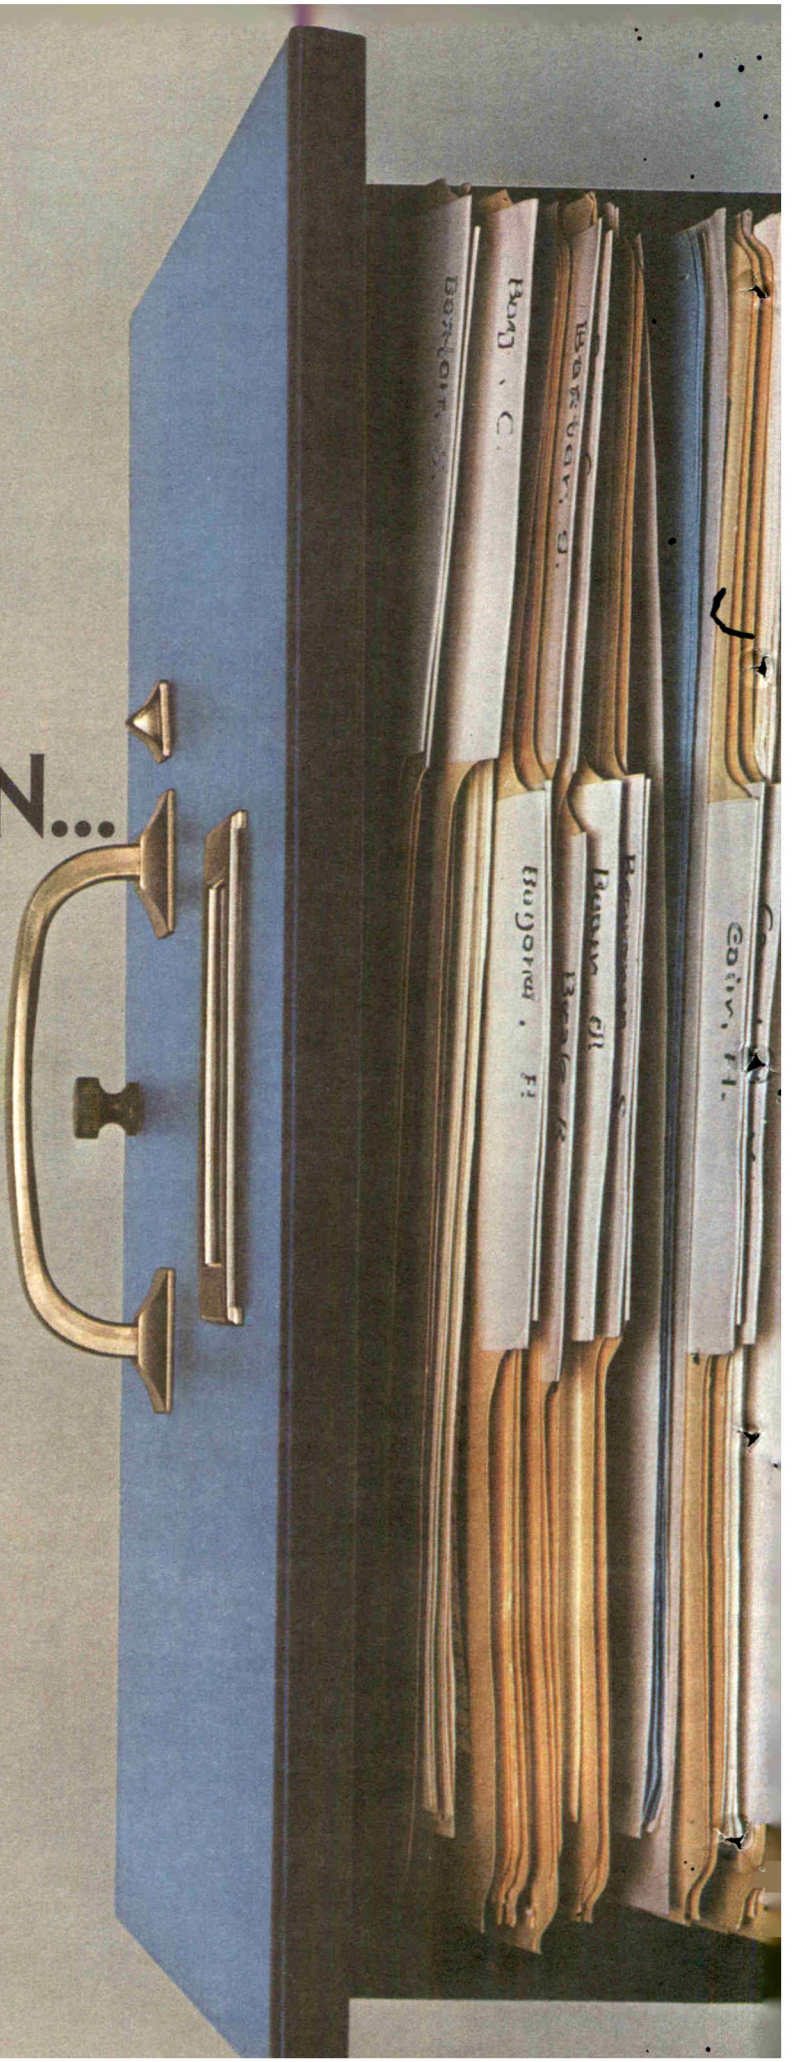
DURATION OF THERAPY: The daily, uninterrupted administration of ANTABUSE must be continued until the patient is fully recovered socially and a basis for permanent self-control is established. Depending on the individual patient, maintenance therapy may be required for months or even years.

TRIAL WITH ALCOHOL: During early experience with ANTABUSE, it was thought advisable for each patient to have at least one supervised alcohol-drug reaction. More recently, the test reaction has been largely abandoned. Furthermore, such a test reaction should never be administered to a patient over 50 years of age. A clear, detailed, and convincing description of the reaction is felt to be sufficient in most cases.

However, where a test reaction is deemed necessary, the suggested procedure is as follows:

After the first one to two weeks' therapy with 500 mg. daily, a drink of 15 cc. (½ oz.) of 100 proof whiskey or equivalent is taken slowly. This test dose of alcoholic beverage may be repeated once only so that the total dose does not exceed 30 cc. (1 oz.) of whiskey. Once a reaction develops, no more alcohol should be consumed. Such tests should be carried out only when the patient is hospitalized, or comparable supervision and facilities, including oxygen, are available.

MANAGEMENT OF ANTABUSE (DISULFIRAM)-ALCOHOL REACTION: In severe reactions, whether caused by an excessive test dose or by the patient's unsupervised ingestion of alcohol, supportive measures to restore blood pressure and treat shock should be instituted. Other recommendations include: oxygen, carbogen (95 per cent oxygen and 5 per cent carbon dioxide), vitamin C intravenously in massive doses (1 Gm.), and ephedrine sulfate. Antihistamines have also been used intravenously. Potassium levels should be monitored particularly in patients on digitalis since hypokalemia has been reported.



HOW SUPPLIED: No. 809—Each tablet (scored) contains 250 mg. disulfiram, in bottles of 100. No. 810—Each tablet (scored) contains 500 mg. disulfiram, in bottles of 50 and 1,000.

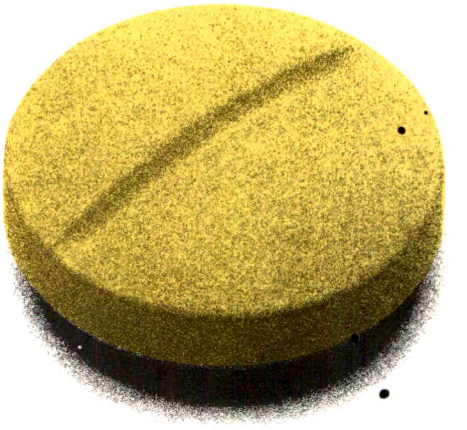
ROCHE

Introducing

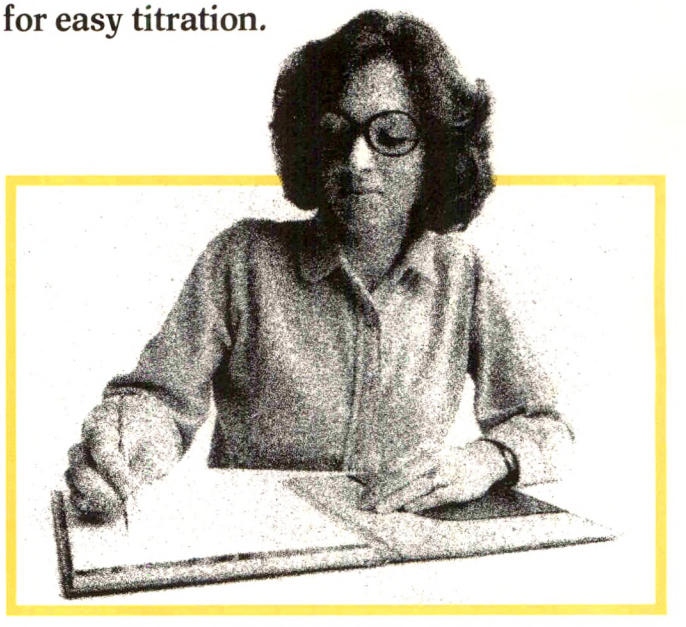
The unforgettable antidepressant



Endep™ 75 mg

amitriptyline HCl / Roche

Here's what makes it unforgettable



Patients are more likely to remember the single bedtime dosage of Endep (amitriptyline HCl).

You'll remember 1 or 2 tablets *h.s.*, because fewer forgotten doses produce a more consistent clinical effect, and because it is the only tricyclic antidepressant scored for easy titration.

Patients will also remember family/interpersonal relationships that they have forgotten or neglected.

In three or four weeks patients will usually remember how well they used to feel.

Endep™ 75 mg

amitriptyline HCl/Roche

The antidepressant you can prescribe at night to work all day

Before prescribing, please consult complete product information, a summary of which appears on the following page.

Introducing Endep™

amitriptyline HCl/Roche

The antidepressant you can prescribe at night to work all day

(orange)	(orange)	(orange)	(yellow)
10-mg scored tablets	**25-mg** scored tablets	**50-mg** scored tablets	**75-mg** scored tablets

■ Endep (amitriptyline HCl), in responsive patients, lifts mood and relieves symptoms such as anorexia, loss of interest, inability to concentrate, decreased libido or GI disturbances, often within three or four weeks after starting therapy.

■ Endep usually relieves accompanying sleep disturbances, particularly early in the treatment regimen.

■ All four dosage strengths are scored for greater flexibility and convenience in titration.

■ The 75-mg *h.s.* dose minimizes skipped doses, maximizes patient acceptance and compliance.

■ Specifying Endep/Roche assures quality plus potential economy.

Important Considerations

Should not be given concomitantly with an MAO inhibitor.

Not recommended for use during the acute recovery phase following myocardial infarction.

Contraindicated in patients with hypersensitivity to amitriptyline.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depression) and depression accompanied by anxiety.

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh potential benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia. purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Dosage: Initiate at low levels; increase gradually, watching for signs of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier. *Initial Adult Dosage:* Outpatients – 25 mg t.i.d.; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate – 50 to 100 mg h.s., gradually increasing h.s. dose up to 150 mg/day. Hospitalized Patients – Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day. *Adolescent and Elderly Patients:* In general, 10 mg t.i.d. with 20 mg h.s. may be satisfactory for those who do not tolerate higher doses. *Maintenance Dosage:* With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg b.i.d. to q.i.d., or 10 mg q.i.d. Continue maintenance therapy 3 months or longer to avoid relapse.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

Supplied: 10-mg, 25-mg, 50-mg and 75-mg scored tablets – bottles of 100 and 500; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg), available singly and in trays of 10.

New APA Task Force Reports

Behavior Therapy in Psychiatry

This comprehensive report reviews the historical development of behavior therapy, its efficacy for the treatment of psychiatric problems, its current forms and uses as well as potential abuses, and its relationship to dynamic psychiatry. Approved for publication by the APA Council on Research and Development, the Report was prepared by a Task Force comprising Lee Birk, M.D., John Paul Brady, M.D., Alan J. Rosenthal, M.D., W. Douglas Skelton, M.D., Joseph B. Stevens, M.D., and Consultants Stephanie B. Stolz, Ph.D., Joseph V. Brady, Ph.D., Arnold A. Lazarus, Ph.D., James J. Lynch, Ph.D., and Edwin J. Thomas, Ph.D.

Report No. 5 | 75 pages, June 1973 | Single copy $3.50

Patterns of Private Psychiatric Practice

The Present and Future Importance of Patterns of Private Psychiatric Practice in the Delivery of Mental Health Services

This report marks the first formal statement the Association has ever issued delineating the vital role of its private practitioner members in the delivery of mental health services in the U.S. Contains sections on patterns of private practice, the economics of it, the impact of third party payments on it, its relation to the public sector, and an assessment of the overall contribution of the private sector to the treatment of mental illness. Stresses the theme that any national system for the delivery of mental health services must be a "balanced mix" of both the private and public sectors, each reinforcing the other. Approved for publication by the Council on Mental Health Services, the Report was prepared by a Task Force comprising Drs. Ewald Busse, Rogers J. Smith, Reed S. Andrus, Winston Cochran, Albert A. Lorenz, Robert L. Leopold, Louis W. Nie, and Consultants Alan I. Levenson, Zigmond M. Lebensohn, Walter E. Barton, and Mr. Robert L. Robinson.

Report No. 6 | 29 pages, June 1973 | Single copy $2.00

Megavitamin and Orthomolecular Therapy in Psychiatry

This comprehensive report reviews and evaluates claims for the effectiveness of the megavitamin rationale, clinical trials of NA and NAA with criticisms and attempts at replication, early clinical trials and attempts at replication, pellagra, schizophrenia and the question of NAD, the diagnosis of schizophrenia, patient selection, and specific phase-treatment programs of orthomolecular psychiatrists, quantitative aspects of megavitamin therapy, incompatibility of Methyl-receptor and NAD positions, and toxicity. Published with the approval of the Council on Research and Development, the Report was prepared by a Task Force comprising Drs. Morris Lipton, Thomas A. Ban, Francis J. Kane, Jerome Levine, and Consultant Richard Wittenborn, Ph.D.

Report No. 7 | 54 pages, June 1973 | Single copy $3.00

Drawing made prior to treatment

Goodenough-Harris Draw-a-Person test from a study in which Cylert was included in the treatment program

Drawing made at week 8 during treatment

Cylert (pemoline) will not in itself "enhance learning" or resolve difficult behavioral problems. But it can increase attention span in the hyperkinetic child and reduce the impulsivity that often interferes with the learning process.

Cylert®
(pemoline)

offers these benefits in a treatment program for MBD

- **Single daily dose administration**
- **Minimal cardiovascular effects**
- **Mean dosage in long-term studies remained remarkably constant**

EFFICACY

Multi-clinic study[1,2]
21 investigators from 10 states and two provinces in Canada took part in the clinical studies.

Double-blind, placebo control
413 patients were randomly assigned to Cylert or placebo groups. 238 patients met all criteria for evaluation of efficacy.

Psychological test results
Children on Cylert had significantly higher scores statistically than those on placebo on these psychological tests:

- The Wechsler Intelligence Scale for Children (WISC) and its performance IQ Sub-Component
- The Wide Range Achievement Test (WRAT) (reading and arithmetic)
- The Lincoln-Oseretsky Motor Performance Test Factor II

Overall results
Approximately two out of three patients were significantly improved by treatment with Cylert as reflected by global ratings.

1. Conners, C. K., ed., *Clinical Use of Stimulant Drugs in Children*, Excerpta Medica, 1974, p. 98.
2. Page, J. G., et al., J. Learning Disabilities, 7:498, Oct., 1974.

SAFETY

Multi-clinic study (9 weeks); safety data analyzed on 407 patients
There was no significant difference between Cylert and placebo groups in:

- Blood pressure
- Laboratory tests
- Pulse
- Neurological status

Insomnia and anorexia were the most frequently seen side effects and often improved with continuation of treatment or reduction of dosage.

Mean weight loss of 1.1 lbs. was demonstrated in the Cylert group during early weeks of treatment; long-term studies have shown that by 3-6 months, most children return to the normal rate of weight gain for their age group.

Long-term study on Cylert; up to 3 years and continuing

Mean dosage . . . remained remarkably constant.
Blood pressure . . no significant changes attributed to Cylert.
Pulse rate . . . . . no significant changes attributed to Cylert.

Laboratory examination—mild to moderate increase in transaminase (SGOT and SGPT) levels in 1-2% of patients (no clinical symptoms); levels returned to normal on withdrawal of medication.

No clinically significant abnormalities in the other tests.

Please see last page of this advertisement for Prescribing Information.

Importance of single daily dosage to the child, the parents and the teacher

For the child		For the adults
No drug in child's possession while at school	⟷	Control of medication remains with parents
Avoids situation in which child is repeatedly singled out as being "different"	⟷	Obviates need for nurse or teacher to supervise taking of mid-day doses
Helps prevent possible variations in effect caused by missed, forgotten or delayed doses	⟷	Helps assure that the prescribed dosage is being given each day

Cylert (pemoline), alone among CNS stimulants used to treat MBD, is inherently long-acting, permitting once-daily dosage.

Cylert can be taken with meals

You can prescribe Cylert a.c., p.c., or with meals. Although the speed of absorption is slightly slowed by food, the total absorption is not affected.

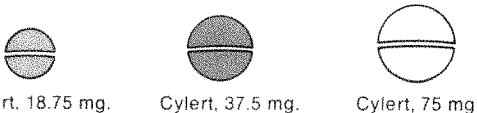
Dosage and administration

Cylert is given as a single oral dose each morning.

The recommended starting dose is 37.5 mg. per day. This daily dosage should be gradually increased at one-week intervals using increments of 18.75 mg. until the desired clinical response is obtained.

The mean daily effective dose ranges from 56.25 to 75 mg. per day. The maximum recommended daily dose of Cylert is 112.5 mg.

Using the recommended schedule of dose titration, significant benefits may not be seen until the third or fourth week of drug therapy. Side effects may be seen prior to optimum clinical results.



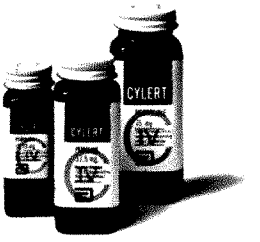
When not to use Cylert

Cylert should not be used for (and will not be effective in) simple cases of overactivity in school-age children.

Neither should it be used in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

The three dosage strengths of Cylert (pemoline)



Cylert, 18.75 mg. (yellow-colored, grooved)

Cylert, 37.5 mg. (orange-colored, grooved)

Cylert, 75 mg. (tan-colored, grooved)

Tablets are actual size.

Cylert (PEMOLINE) CIV

Prescribing Information

Description: Cylert (pemoline) is a white, tasteless, odorless powder which is relatively insoluble (less than 1 mg/ml) in water, chloroform, ether, acetone, and benzene. In 95% ethyl alcohol, the solubility of pemoline is 2.2 mg/ml.

Actions: Cylert (pemoline) is a central nervous system stimulant. The pharmacologic activity of pemoline is similar to that of other known stimulants but with minimal sympathomimetic effects. Pemoline is structurally dissimilar from the amphetamines and methylphenidate. Although the exact mode of pharmacodynamic action is undetermined in man, pemoline has been reported to increase the rate of synthesis of dopamine in rat brain.

In human subjects, Cylert produces peak blood levels within 2-4 hours. The serum half-life is approximately 12 hours. Multiple dose studies in adults at several dose levels indicate that serum levels plateau in approximately three days. Cylert and its metabolites are primarily excreted by the kidneys with approximately 75% of an oral dose appearing in the urine within a 24-hour period. Approximately 43% of pemoline is excreted unchanged. Metabolites include pemoline dione, conjugated pemoline and mandelic acid.

Cylert (pemoline) has a gradual onset of action in children with minimal brain dysfunction. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

Indications: MINIMAL BRAIN DYSFUNCTION IN CHILDREN—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations:

Specific etiology of minimal brain dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis includes the use not only of medical but of psychological, educational, and social resources.

Characteristics commonly reported include: A chronic history of moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindication: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See PRECAUTIONS)

Warnings: Cylert is not recommended for children under six years of age since safety and efficacy in this age group have not yet been established.

Since Cylert (pemoline) and its metabolites are excreted primarily by the kidneys, caution should be observed in administering the drug to children with significantly impaired renal function.

Sufficient data on safety and efficacy of Cylert administration for periods beyond two years duration in children with minimal brain dysfunction are not yet available. Although a definite causal relationship has not been established, some temporary suppression of predicted growth pattern(i.e., weight and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Drug Interactions: Interactions between Cylert and other drugs have not been studied in humans. As with most other drugs, concurrent administration with other agents, especially drugs with central nervous system activity, should be carefully monitored.

Usage in Pregnancy: Safety for use in pregnancy has not been established. Standard studies of fertility, teratology and reproduction were conducted in rats and rabbits. Daily oral doses of pemoline of 18.75 and 37.5 mg/kg beginning at conception produced no abnormalities in the fetuses and did not affect viability at birth. Further studies using similar dose levels with drug administration beginning 14 days before conception demonstrated an increased incidence of stillbirths in these animals.

Drug Dependence: Studies of the drug abuse potential of Cylert (pemoline) in primates have not demonstrated a potential for self-administration. However, the pharmacologic similarities between Cylert and other CNS stimulants with known abuse liability suggest that drug dependence of the stimulant type might occur. There have been isolated reports of transient psychotic symptoms in adults following long-term misuse of pemoline taken orally in excessive quantities. Therefore, caution should be observed in emotionally unstable patients considered to have a psychological potential for drug dependence.

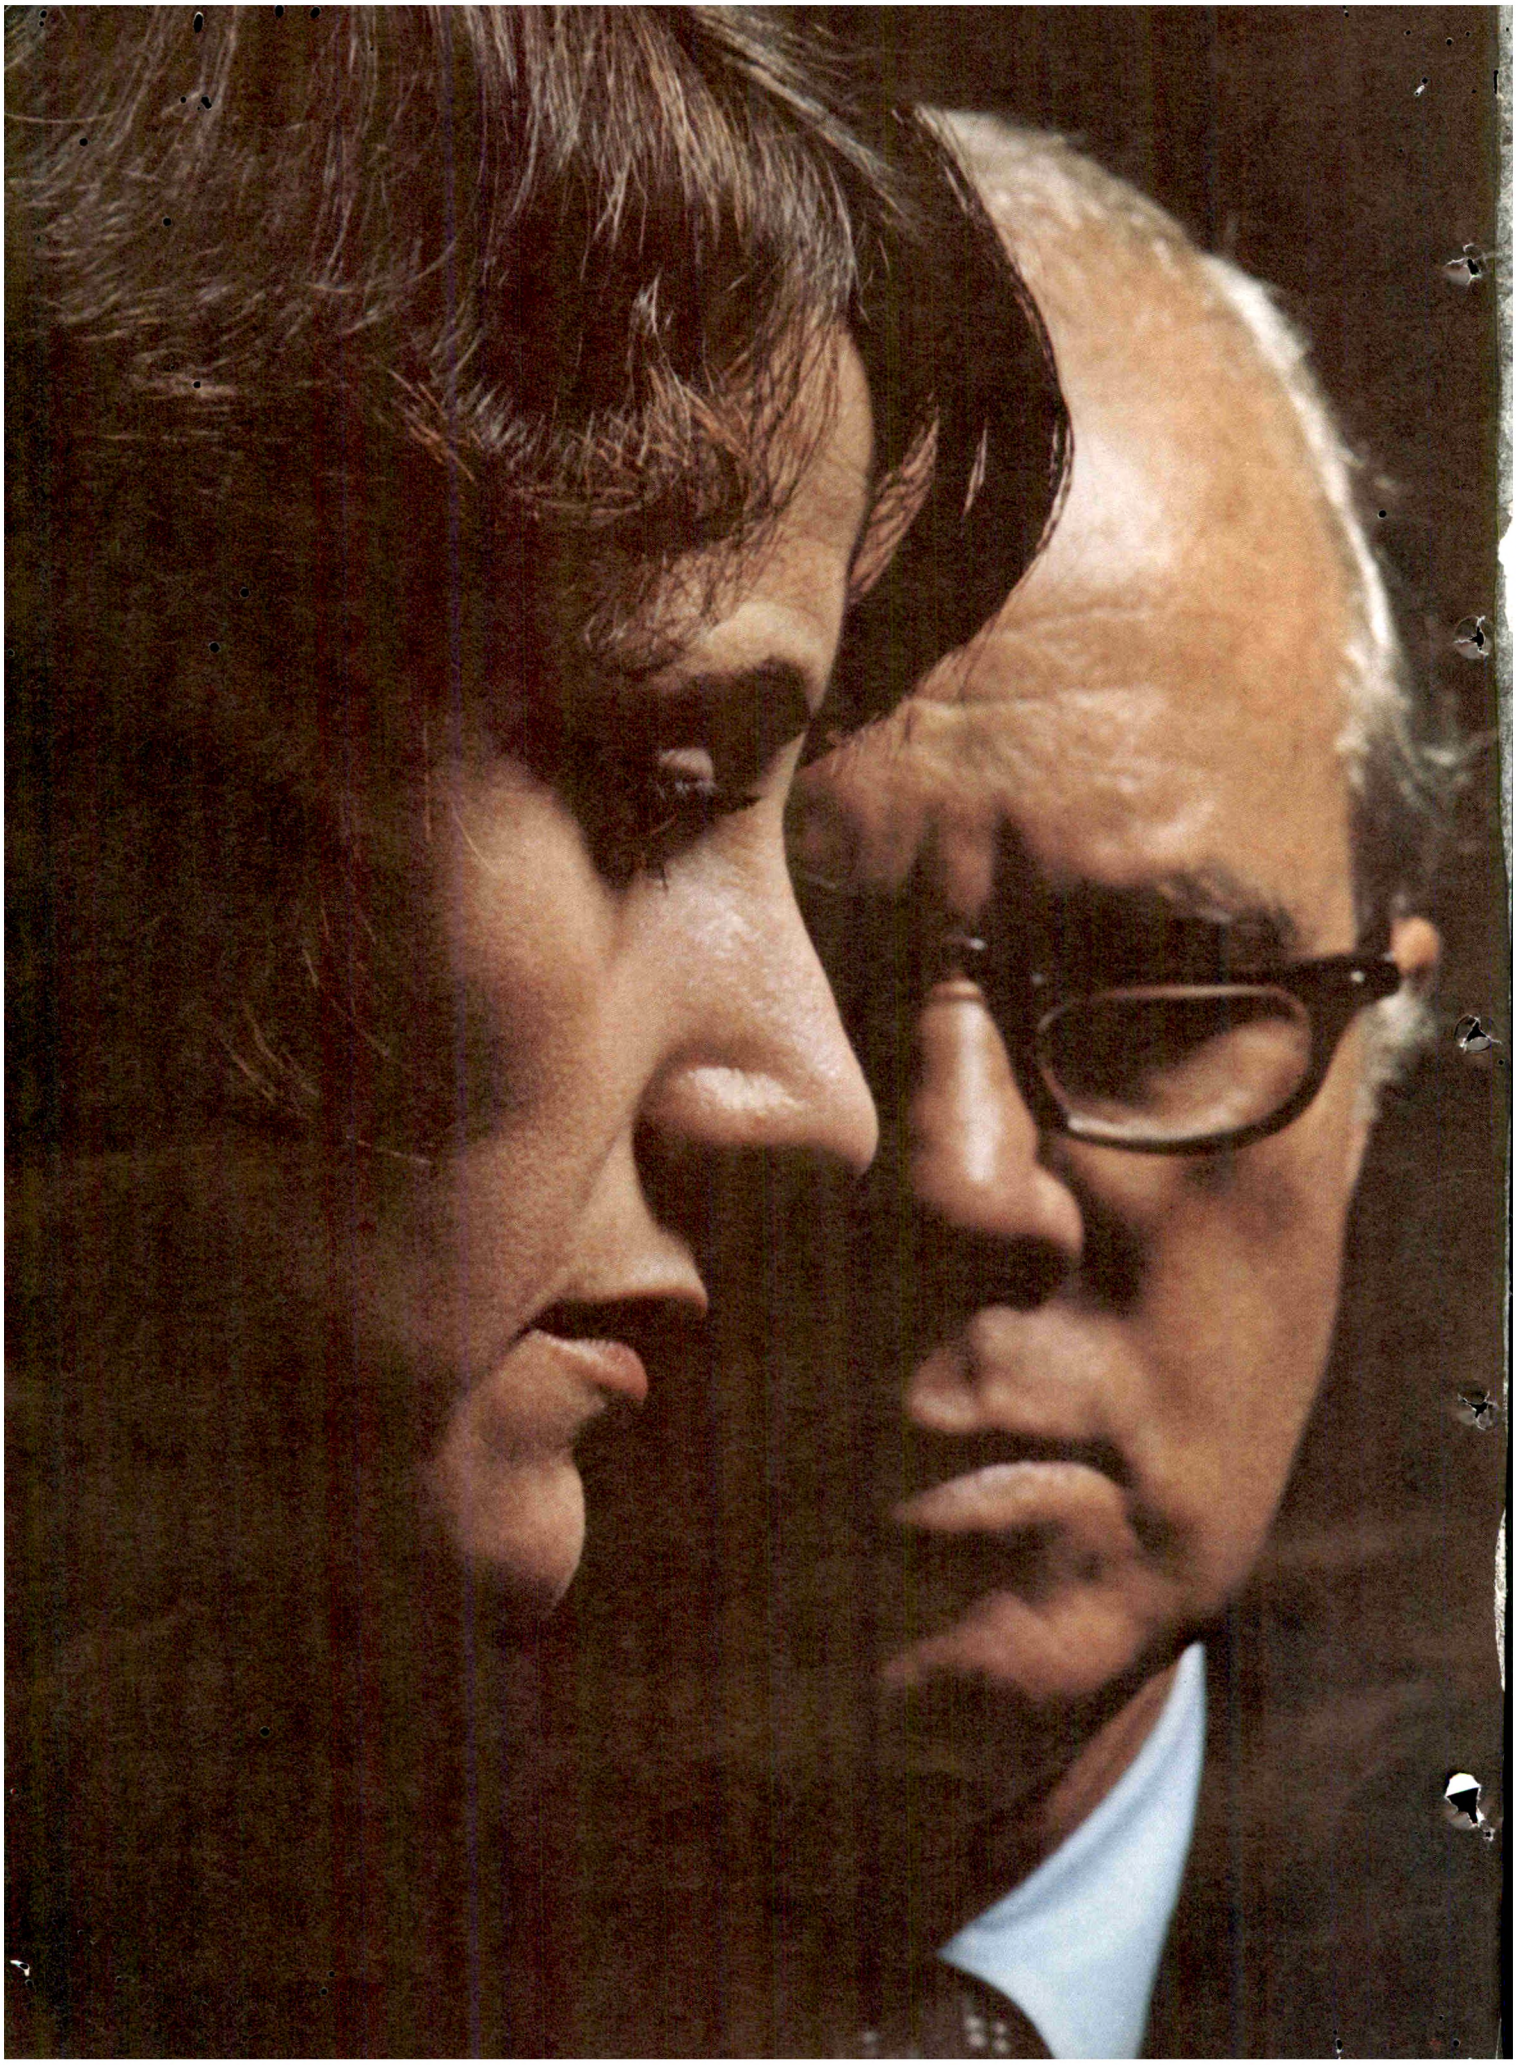
Precautions: Delayed hypersensitivity reactions involving the liver have been reported in 1-2% of the patients receiving Cylert usually after several months of therapy. No clinical symptomatology has been observed, but mild to moderate increases in transaminase (SGOT and SGPT) levels have occurred in these cases. These effects appear to be completely reversible when drug treatment is discontinued. Transaminase levels should be determined periodically during therapy with Cylert to detect any such reactions.

Adverse Reactions: The most frequently reported adverse reaction with Cylert is insomnia. Insomnia has been observed prior to optimum therapeutic response and in the majority of cases was transient in nature or responded to dosage reduction. Anorexia with weight loss during the first few weeks of therapy has also been reported. With continuing therapy, a return to a normal weight curve usually occurred within three to six months. Other adverse reactions reported include stomachache, skin rash, irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations. Mild adverse reactions appearing early in treatment often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage reduction or discontinuation should be considered.

Dosage and Administration: Cylert (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg per day. This daily dosage should be gradually increased at one week intervals using increments of 18.75 mg until the desired clinical response is obtained. The mean daily effective dose ranges from 56.25 to 75 mg per day. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with Cylert is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration. Drug administration should be interrupted occasionally to determine if behavioral symptoms sufficient to require continuing therapy recur.

Overdosage: Cylert overdosage has been reported to produce symptoms of tachycardia, hallucinations, agitation, or restlessness. The treatment of acute massive overdosage with pemoline is essentially the same as that for overdosage with any drug having CNS stimulatory effects. Management is largely symptomatic and may include induction of emesis, gastric lavage or other measures as appropriate.



How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (yellow-colored) in bottles of 100 (**NDC** 0074-6025-13)

37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6057-13)

75 mg. tablets (tan-colored) in bottles of 100 (**NDC** 0074-6073-13)

ABBOTT LABORATORIES
North Chicago, IL60064 6013128

The TRIAVIL® Potential in the management of moderate to severe anxiety with depression

When time and talk are not enough...
The therapist is the primary catalyst for change in the psychotherapeutic relationship. However, when patients suffer from moderate to severe anxiety with depression, there are situations when TRIAVIL can often be a useful adjunct.

...TRIAVIL may help
There are three important benefits you may expect when TRIAVIL is part of the treatment program: (1) When symptoms of moderate to severe anxiety or agitation with depression are relieved, the patient may become more accessible and cooperative. (2) As somatic manifestations are controlled, attention may be focused on underlying causative factors. (3) Symptomatic relief may enable the patient to function more effectively in his daily life while your work with the patient progresses.

Tablets TRIAVIL are available in four different combinations affording flexibility and individualized dosage adjustment. Since it is simpler to remember to take one tablet rather than several (particularly in multiple daily doses), your patients on TRIAVIL will be more likely to take proper doses of the medication.

TRIAVIL is contraindicated in CNS depression from drugs; in the presence of evidence of bone marrow depression; and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please turn to the following page.

when patients exhibit moderate to marked anxiety or agitation with symptoms of depression

TRIAVIL® **containing perphenazine and amitriptyline HCl**

a tranquilizer-antidepressant

for highly effective relief of depression with moderate anxiety

TRIAVIL®

containing perphenazine and amitriptyline HCl
a tranquilizer-antidepressant

Available:

TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl

TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Do not give concomitantly with MAOI drugs because hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. Allow minimum of 14 days between therapies, then initiate therapy with TRIAVIL cautiously, with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given with guanethidine or similarly acting compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, particularly in high doses, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. Caution patients performing hazardous tasks, such as operating machinery or driving motor vehicles, that drug may impair mental and/or physical abilities. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Side effects may be any of those reported with phenothiazine drugs: extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and that the full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; hypnotic effects; pigmentary retinopathy; corneal and lenticular pigmentation; occasional lassitude, muscle weakness, mild insomnia. Other adverse reactions reported with various phenothiazine compounds include blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); liver damage (jaundice, biliary stasis); grand mal convulsions; cerebral edema; polyphagia; photophobia; skin pigmentation; and failure of ejaculation.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness; weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; jaundice; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

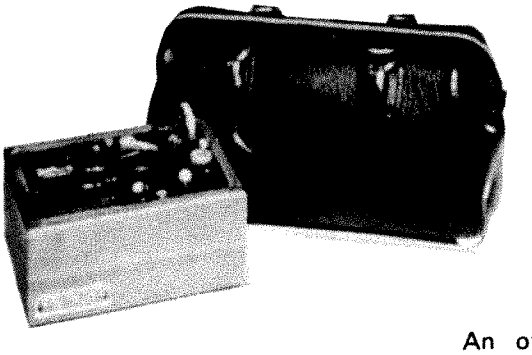
MSD
MERCK SHARP & DOHME

MORE THAN 30 YEARS...

have proven the dependability and effectiveness of REITER ELECTROSTIMULATORS in psychiatry! Research and constant improvements to meet the standards of improved techniques have kept Reiter instruments

THE WORLD'S MOST ACCEPTED ELECTROSTIMULATORS

The Two Popular Models— **PORTABLE FOR OFFICE AND CLINIC**



The Reiter MODEL SOS—THE ONE INSTRUMENT FOR ALL ESTABLISHED TECHNIQUES, provides the fullest range of safest therapies. For painless, gentle stimulation of the conscious patient to relieve anxiety, depression, etc. Maximum safety, no additives—patient conscious and cooperating with therapy.

The SOS has also been used universally for Convulsive Therapy, Non-Convulsive Therapies, Electro-Sleep Therapy, Focal Treatment, Mono-Polar Treatment, Barbiturate Coma (and other respiratory problems), Mild Sedac, Deep Sedac Therapy, Pre-Convulsive Sedac, Post-Convulsive Sedac, Neurological Conditions, and Measurement Procedures.

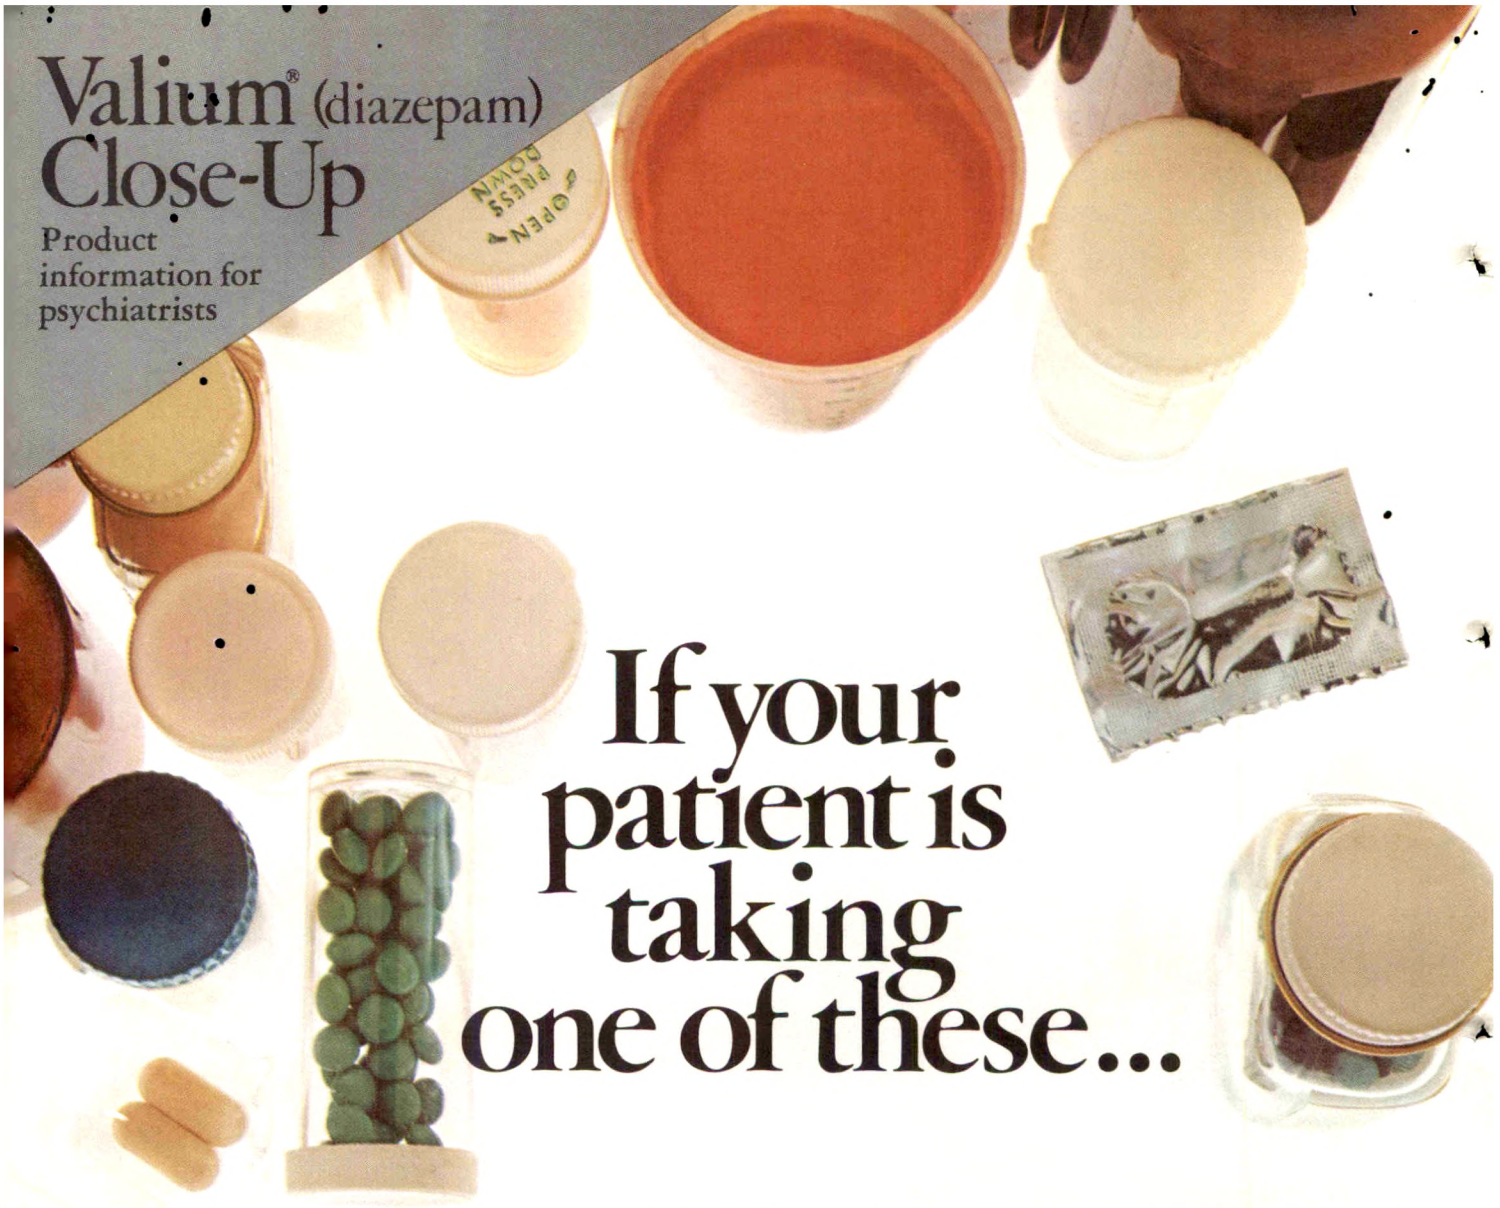
Available with this redesigned model, on request, the following special-purpose electrodes —a Multi-Polar "Collar" type for Sleep Therapy, a "Horseshoe" assembly for quicker, surer application with one hand at last moment before ECT treatment, and a "Unilateral" type assembly.

Also built-in on request, an **automatic switch** for quicker build up to therapeutic ranges of Sedac.

SPECIAL MODEL SOS available without unidirectional convulsive current.

The Reiter Compact MOL-AC II—The smallest, lightest, least expensive and most reliable, clinically proven A.C. shock therapy instrument. Less confusion than from similar A.C. equipment. Now available with redesigned, improved panel. This compact instrument is only 3 x 5 inches, weighs but 3 lbs., yet provides full positive control of glisando effect over entire voltage range, as well as a positive manual control of time. There are NO complicated settings of dials, NO waiting for resetting of time devices, no warm-up delays.

An officially approved, extremely durable instrument which has earned world-wide professional acceptance, the MOL-AC II is economically priced with a fine, genuine leather physician's bag included.



Other Models Still Available: The CW47, original therapeutic cerebral stimulator with only 3 of the 9 treatment current selections available on Model SOS.

Valium® (diazepam) Close-Up

Product information for psychiatrists

If your patient is taking one of these...

Primary medications

anticoagulants
antacids
cardiac glycosides
diuretics
vasodilators
anticholinergics

Psychotropics/CNS depressants

alcohol
phenothiazines
narcotics
barbiturates
hypnotics
MAO inhibitors
minor tranquilizers
antidepressants

Anticonvulsants

ROCHE

you should know this about Valium® (diazepam)

Valium is frequently used with most classes of these primary medications. Clinically significant drug interactions have not been reported to date.

Potentiation may occur with other CNS depressants. Careful consideration should be given to the pharmacology of these compounds when used concomitantly with Valium.

As with other agents which have anticonvulsant activity, the possibility of increase in frequency and/or severity of grand mal seizures may require an increase in dosage of standard anticonvulsants.

Valium® (diazepam)

2-mg, 5-mg, 10-mg scored tablets ℞

Before prescribing, please see following

Valium® (diazepam)

2-mg, 5-mg, 10-mg scored tablets

can relieve psychoneurotic anxiety and its associated depressive symptoms

Prompt, effective action. Valium works rapidly to relieve pronounced psychic tension in patients overreacting to stress and in psychoneurotic patients.

Wide margin of safety. Valium is generally well tolerated and in usual dosages rarely produces significant adverse reactions.

Dosage flexibility. Scored Valium 2-, 5-, 10-mg tablets give you dosage flexibility no tranquilizer capsule can match.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

Evaluation of Psychological Therapies

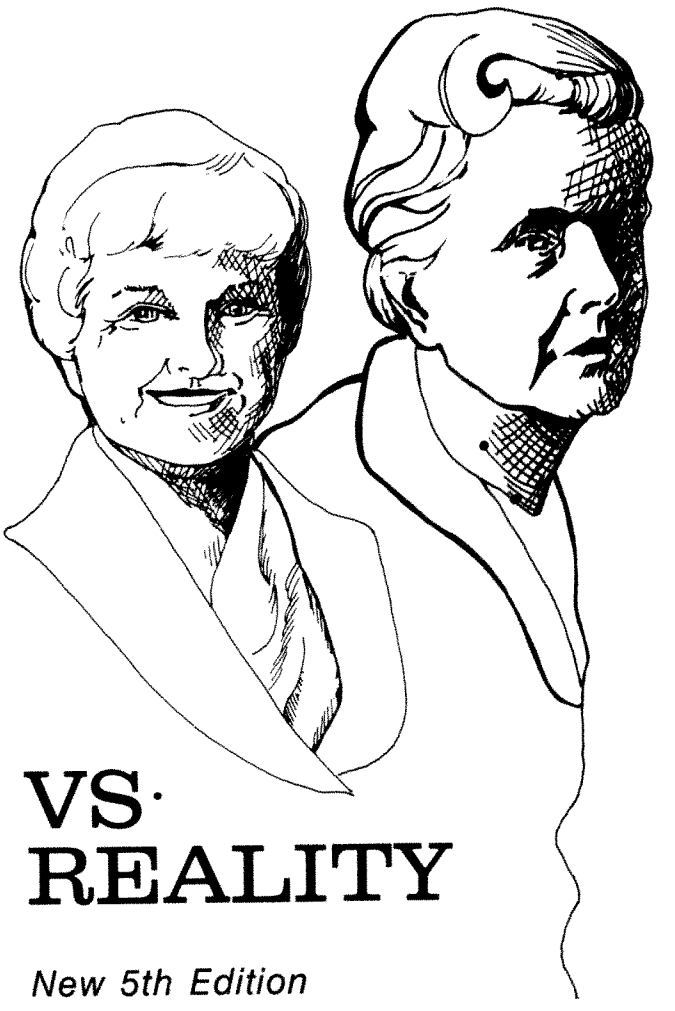
Psychotherapies, Behavior Therapies
Drug Therapies, and Their Interactions

edited by Robert L. Spitzer and Donald F. Klein

The contributors take a searching look at the efficacy and interaction of the most popular psychiatric therapies — individual psychoanalysis and psychotherapy, behavior therapy, and drug-psychological therapies — in treating depression, schizophrenia, behavioral disturbances of children, alcoholism, and various phobias. $17.00

Textbook of Disturbances of Mental Life

Johann Christian Heinroth



Preface by George Mora

Far in advance of his time in his enlightened and humane attitude toward mental illness, Heinroth helped firmly establish psychiatry as being the domain of the physician rather than the philosopher or the theologian. His most significant work in the field of mental pathology is now made available in English for the first time.
Two volumes. $17.50

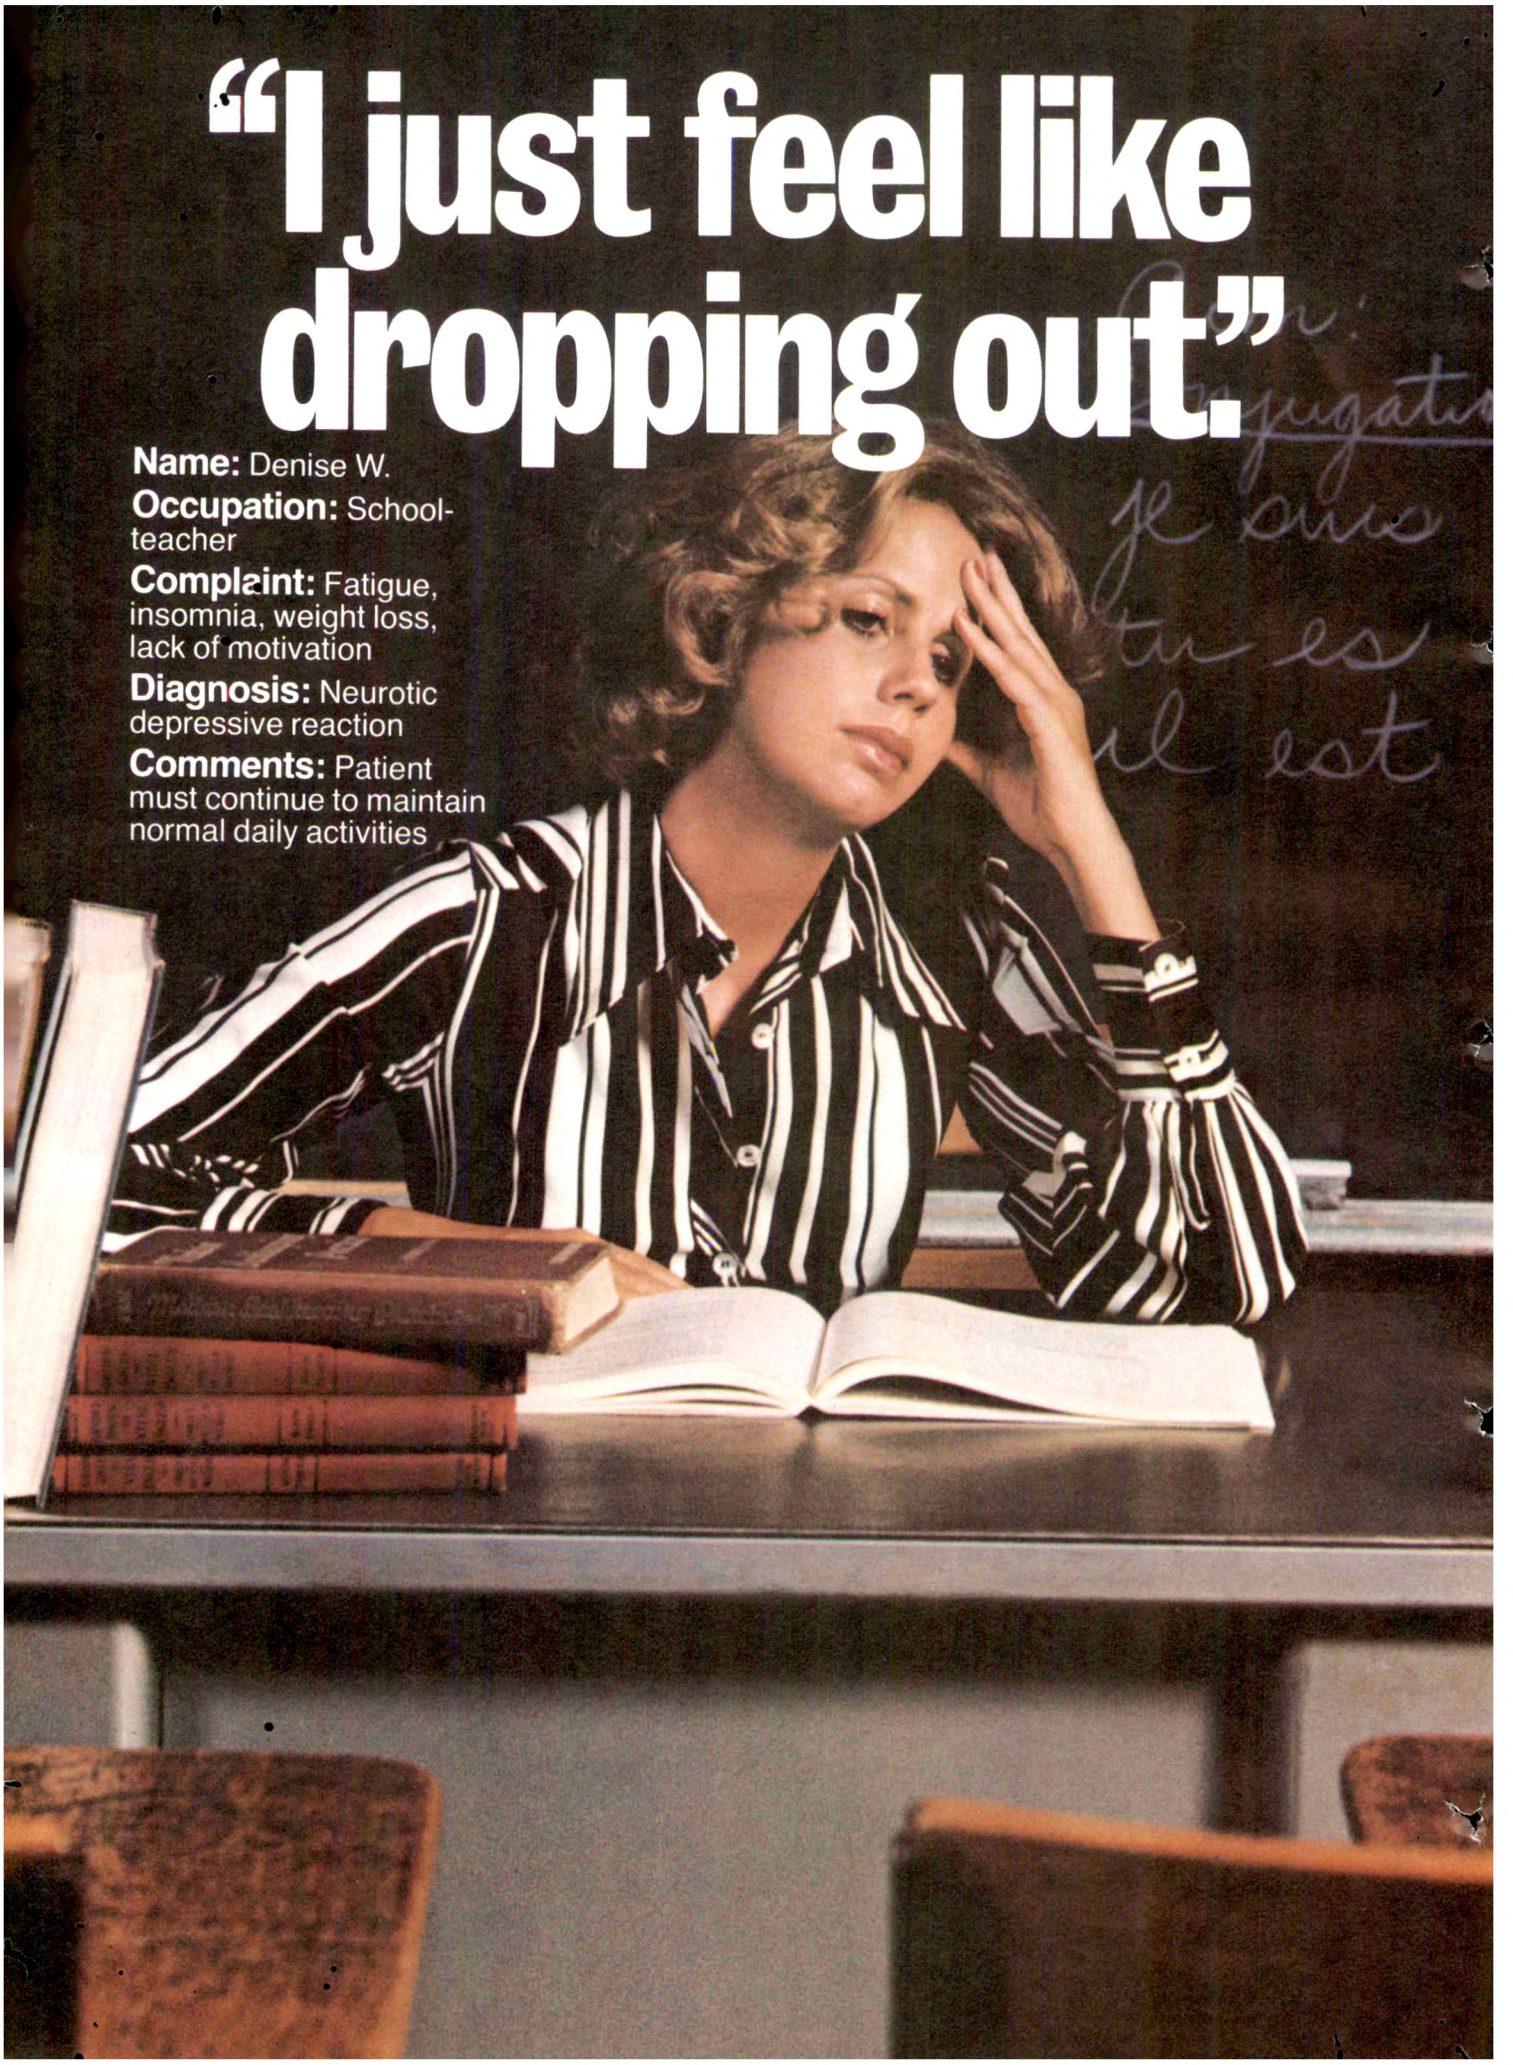
APPEARANCE

VS. REALITY

New 5th Edition

MASK OF SANITY



There is no cure . . . or social, medical, or legal facility that fully recognizes the pathologic disorders of the psychopathic personality (from the Preface). Dr. Hervey Cleckley, renowned psychiatrist and expert in understanding and defining the psychopath, explains the reality behind the mask of sanity worn by psychopaths. Now available in a new 5th edition, Dr. Cleckley's classic work presents careful, clinical observations and working hypotheses on psychopathy. Clinical anecdotes and updated case studies vividly illustrate the most current findings in the field. New references and a new bibliography are included. Major sections in the book outline the problem, present full and incomplete manifestations of the disorder, provide clinical profiles and comparisons, and reveal current controversies and possible rehabilitation.

By Hervey M. Cleckley, M.D. March, 1976. Approx. 544 pages, 6½" x 9½". About $14.95.

"I just feel like dropping out."

Name: Denise W.
Occupation: School-teacher
Complaint: Fatigue, insomnia, weight loss, lack of motivation
Diagnosis: Neurotic depressive reaction
Comments: Patient must continue to maintain normal daily activities

In depression

Proven clinical efficacy

When patient complaints lead you to a diagnosis of depression, "...desipramine is an effective antidepressant...The most effective results occurred in those patients in whom the primary diagnosis was a psychoneurotic depressive reaction."[1] Such efficacy has been well documented[1-4] in over a decade of clinical use.

Prompt therapeutic response

Several studies have shown that Pertofrane may have a rapid onset of therapeutic action. This relatively rapid onset of action is particularly useful when patients must *continue* to function actively on their jobs or at home.

Mid-range sedation

"There is no problem of drowsiness."[1] Pertofrane shows good to excellent antidepressant effect yet is only mid-range in sedation[5]—especially important when patients must maintain normal levels of daily activity.

Compatible with tranquilizers/sedatives

When indicated, Pertofrane may be used with tranquilizers or sedatives.[1] This allows valuable flexibility in the individualization of therapy to the specific needs of the patient whose mild anxiety or agitation, which accompanies his depression, does not remit to Pertofrane alone.

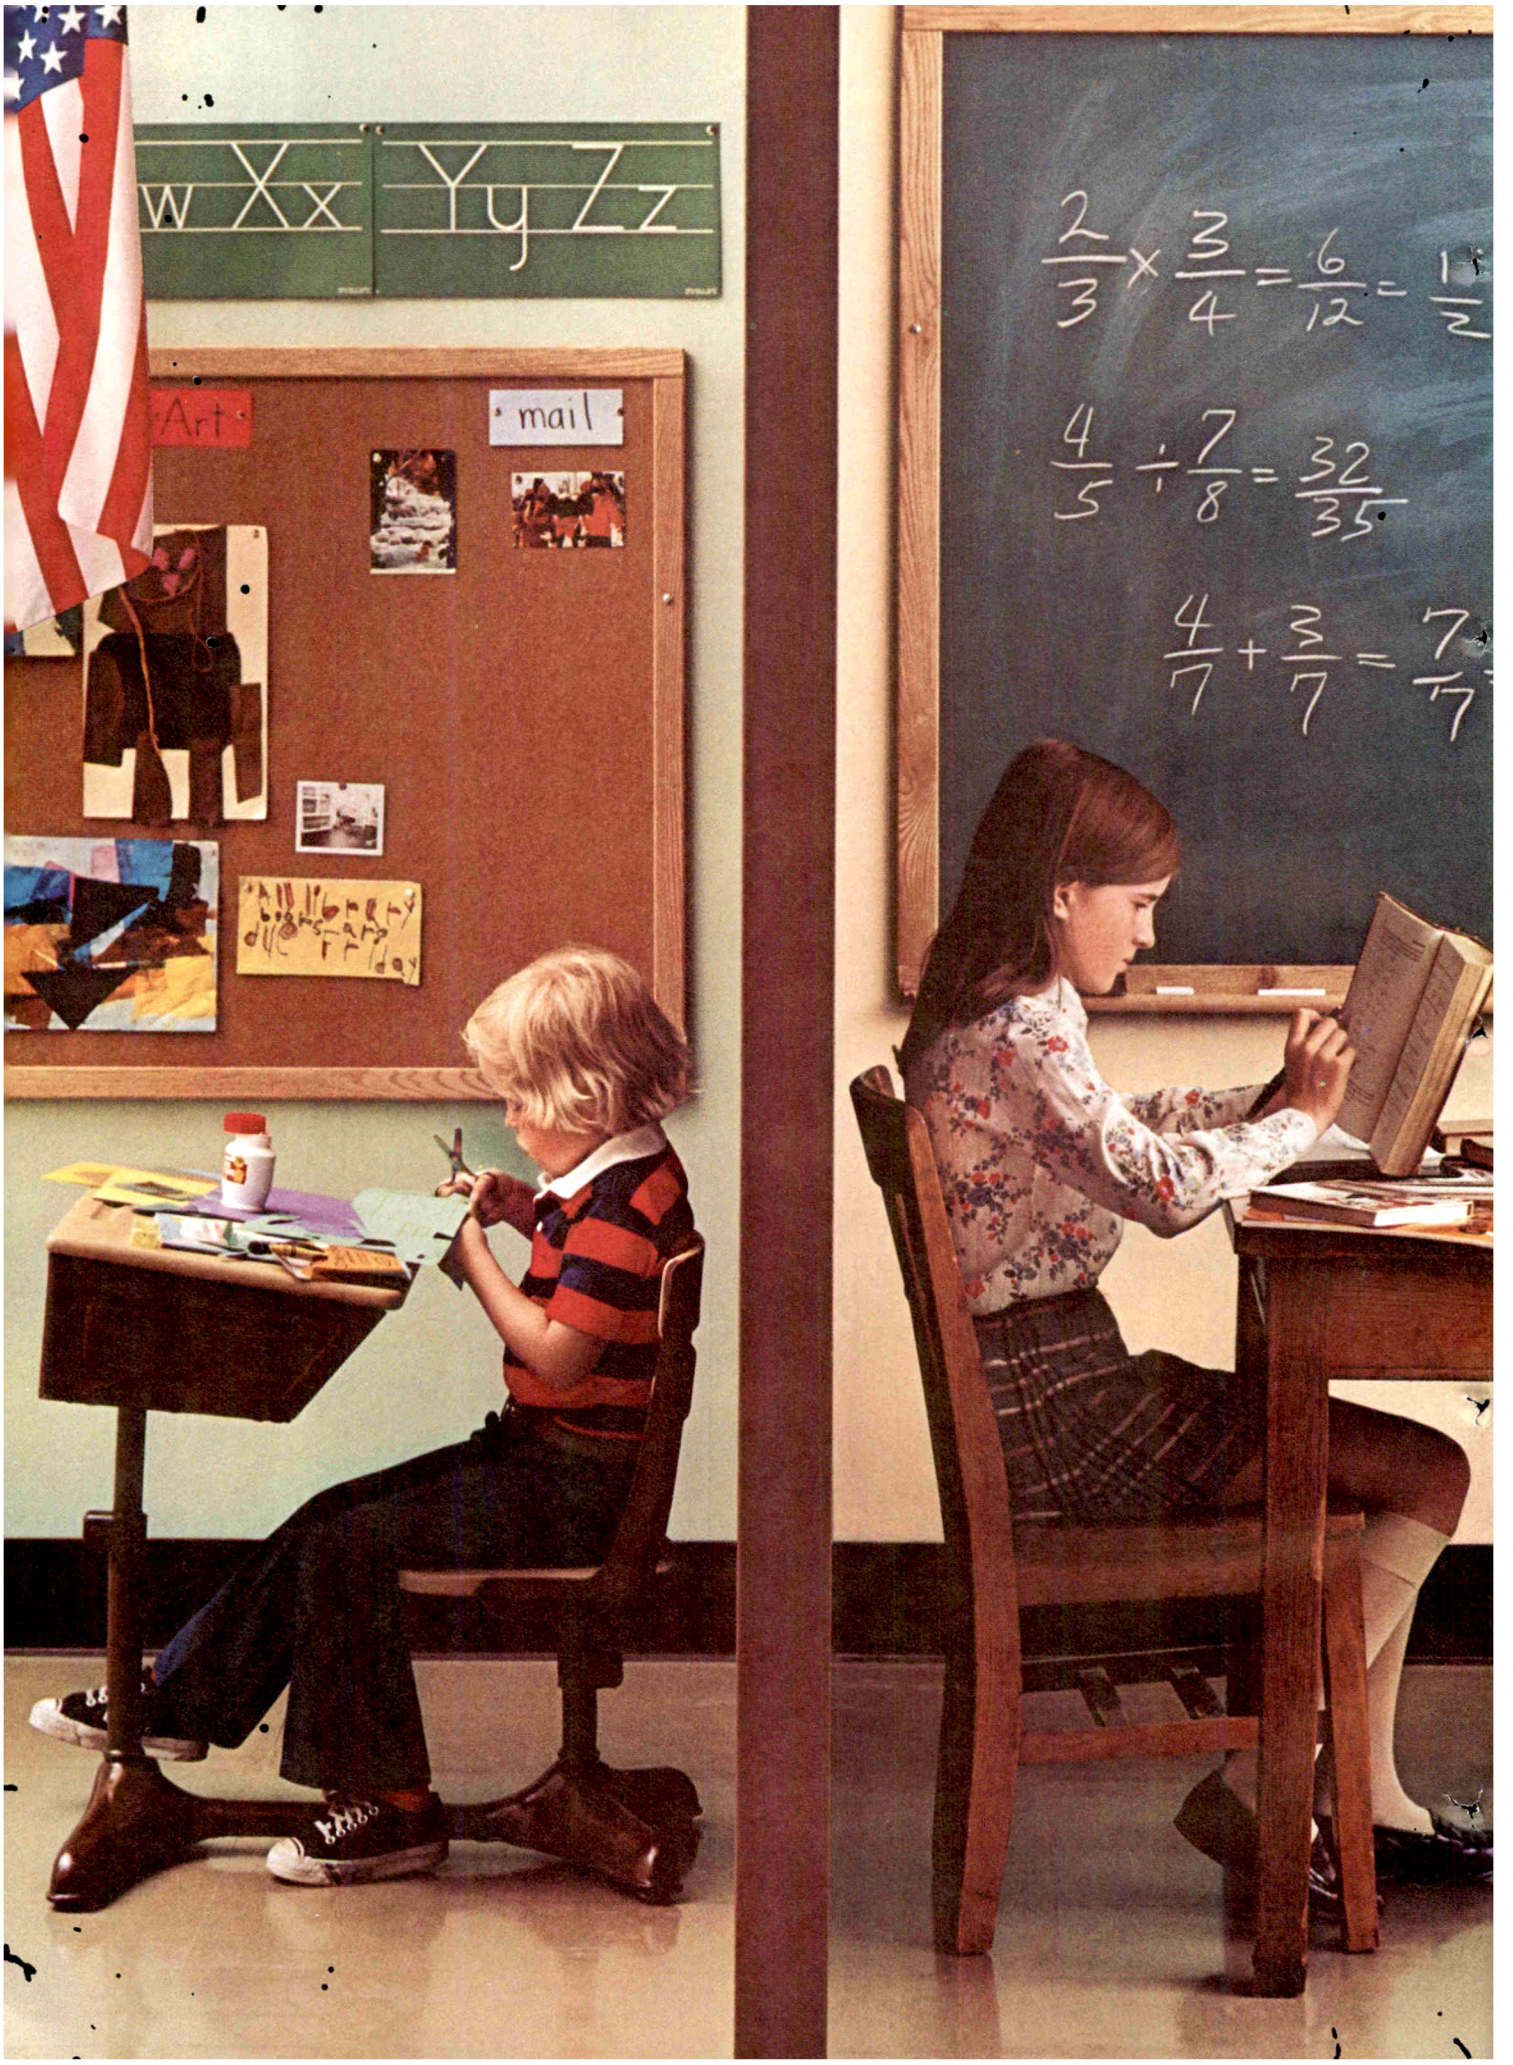
Pertofrane®



(desipramine hydrochloride NF)

When activity is important

USV PHARMACEUTICALS

USV Pharmaceutical Mfg. Corp.
Manati, P.R. 00701

Indication: For relief of mental depression. **Contraindications:** Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises or severe convulsive seizures may occur with such combinations; potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane (desipramine HCl) in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings:** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG patterns, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice (apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine. **Dosage:** All patients except geriatric and adolescent: 50 mg. t.i.d. (150 mg. daily). Dosage may be increased up to 200 mg. daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg. daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Mild anxiety and agitation which may accompany depression usually remit as the depression responds. Occasionally, however, a sedative or tranquilizer may be indicated. **How Supplied:** 25 mg. capsules (pink), bottles of 100 and 1000. Also, 50 mg. capsules (maroon and pink), bottles of 100 and 1000; single-dose blister packs, boxes of 500.

The vulnerable ages

The first epileptic seizure is most likely to occur during early childhood and at the onset of puberty

About 9 out of 10 epileptics experience their first seizure before the age of 20—with the highest incidence between 5 and 7, when children start school, and at the onset of puberty, a time of physiological and psychic turmoil.[1] The most common type, grand mal, occurs in approximately 75% of epileptic children,[1] and more than 50% of patients who suffer initially from petit mal develop grand mal seizures before they reach the age of 16.[2]

Mysoline (primidone) for control of grand mal, psychomotor and focal epilepsy

At the onset and afterwards— used alone or as concomitant therapy, MYSOLINE may reduce the frequency and severity of major motor seizures—or even eliminate them. *Excellent* for control of grand mal. Valuable for control of psychomotor[1,3,4] and focal epilepsy as well.[5]

Add Mysoline when control with other anticonvulsants is inadequate—As concomitant therapy, MYSOLINE can improve seizure control in grand mal and psychomotor epilepsy. The combined use of phenobarbital, diphenylhydantoin, and MYSOLINE may have additive anticonvulsant effects without additive side effects.[6]

Change to Mysoline when other anticonvulsants fail— A changeover to MYSOLINE is frequently warranted when other anticonvulsants must be discontinued because of important side effects, or when grand mal seizures are refractory to phenobarbital, with or without diphenylhydantoin.[7]

Mysoline® (primidone)

may be the start of a better life for the epileptic

initial and maintenance therapy for
grand mal, psychomotor and focal epilepsy

BRIEF SUMMARY
(For full prescribing information, see package circular.)

MYSOLINE® Brand of PRIMIDONE
Anticonvulsant

ACTIONS: MYSOLINE acts on the central nervous system to raise seizure threshold or alter seizure pattern. The mechanism(s) of action of anticonvulsant drugs is not known.

Primidone has anticonvulsant activity *per se*. In addition, its two metabolites possess anticonvulsant qualities. The major metabolite is phenylethylmalonamide (PEMA); the other is phenobarbital. In addition to its own anticonvulsant potential, PEMA potentiates phenobarbital.

INDICATIONS: MYSOLINE, either alone or used concomitantly with other anticonvulsants, is indicated in the control of grand mal, psychomotor, and focal epileptic seizures. It may control grand mal seizures refractory to other anticonvulsant therapy.

CONTRAINDICATIONS: Primidone is contraindicated in: 1) patients with porphyria and 2) patients who are hypersensitive to phenobarbital (see ACTIONS).

WARNINGS: The abrupt withdrawal of antiepileptic medication may precipitate status epilepticus.

The therapeutic efficacy of a dosage regimen takes several days before it can be assessed.

Use in pregnancy: Recent reports strongly suggest an association between the use of anticonvulsant drugs by women with epilepsy and an elevated incidence of birth defects in children born to these women. Reference has been made to primidone in several cases in which it was used *in combination* with other anticonvulsants; but its teratogenicity has not been conclusively demonstrated. The possibility exists that other factors, *e.g.*, genetic factors or the epileptic condition, may contribute to the higher incidence of birth defects. The data also indicate that the great majority of mothers receiving anticonvulsant medication deliver normal infants.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and risk to both mother and the unborn child.

When the nature, frequency, and severity of the seizures do not pose a clear threat to the patient, good medical practice requires that the physician weigh the expected therapeutic benefit of anticonvulsant therapy against possible risk on an individual basis.

Neonatal hemorrhage, with a coagulation defect resembling vitamin K deficiency, has been described in newborns whose mothers were taking primidone and other anticonvulsants. Pregnant women under anticonvulsant therapy should receive prophylactic vitamin K_1 therapy for one month prior to, and during, delivery.

The physician should weigh all of the foregoing considerations when treating and counseling epileptic women of childbearing potential.

PRECAUTIONS: The total daily dosage should not exceed 2 Gm. Since MYSOLINE therapy generally extends over prolonged periods, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

In nursing mothers: There is evidence that in mothers treated with primidone, the drug appears in the milk in substantial quantities. Since tests for the presence of primidone in biological fluids are too complex to be carried out in the average clinical laboratory, it is suggested that the presence of undue somnolence and drowsiness in nursing newborns of MYSOLINE-treated mothers be taken as an indication that nursing should be discontinued.

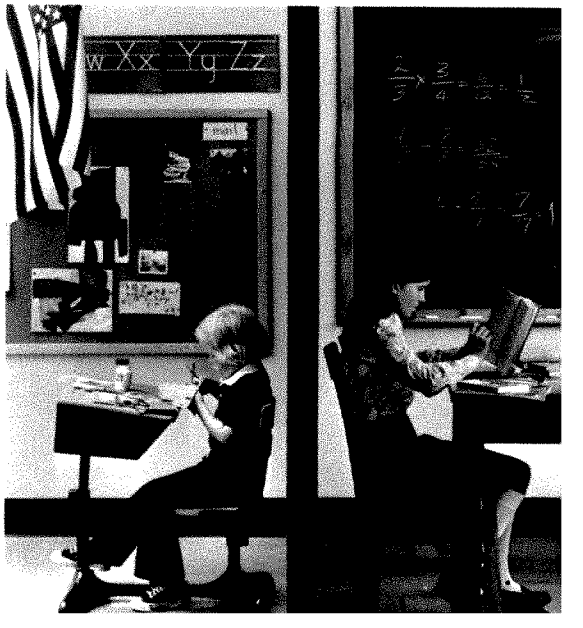
ADVERSE REACTIONS: The most frequently occurring early side effects are ataxia and vertigo. These tend to disappear with continued therapy, or with reduction of initial dosage. Occasionally, the following have been reported: nausea, anorexia, vomiting, fatigue, hyperirritability, emotional disturbances, sexual impotency, diplopia, nystagmus, drowsiness, and morbilliform skin eruptions. Occasionally, persistent or severe side effects may necessitate withdrawal of the drug. Megaloblastic anemia may occur as a rare idiosyncrasy to MYSOLINE and to other anticonvulsants. The anemia responds to folic acid, 15 mg. daily, without necessity of discontinuing medication.

DOSAGE AND ADMINISTRATION: The average adult dose is 0.75 to 1.5 Gm. per day. The initial dose is 250 mg. Increments of 250 mg. are added, usually at weekly intervals, to tolerance, or therapeutic effectiveness, up to daily doses not exceeding 2.0 Gm. A typical dosage schedule for the introduction of MYSOLINE (primidone) is as follows:

Adults and Children Over 8 Years of Age

1st Week 250 mg. daily at bedtime	*2nd Week* 250 mg. b.i.d.
3rd Week 250 mg. t.i.d.	*4th Week* 250 mg. q.i.d.

In children under 8 years of age, maintenance levels are established by a similar schedule, but at one-half the adult dosage. It is best to begin with 125 mg., with gradual weekly increases of 125 mg. a day, to a daily total usually between 500 mg. and 750 mg.



In patients already receiving other anticonvulsants: MYSOLINE should be gradually increased as dosage of the other drug(s) is maintained or gradually decreased. This regimen should be continued until satisfactory dosage level is achieved for combination, or the other medication is completely withdrawn. When therapy with this product alone is the objective, the transition should not be completed in less than two weeks.

MYSOLINE 50 mg. Tablet can be used to practical advantage when small fractional adjustments (upward or downward) may be required, as in the following circumstances:

- for initiation of combination therapy
- during "transfer" therapy
- for added protection in periods of stress or stressful situations that are likely to precipitate seizures (menstruation, allergic episodes, holidays, etc.)

HOW SUPPLIED: MYSOLINE *Tablets*—No. 430—Each tablet contains 250 mg. of primidone (scored), in bottles of 100 and 1,000. Also in unit dose package of 100. No. 431—Each tablet contains 50 mg. of primidone (scored), in bottles of 100 and 500. MYSOLINE *Suspension*—No. 3850—Each 5 cc. (teaspoonful) contains 250 mg. of primidone, in bottles of 8 fluid ounces.

I CLI ICALLY SIG IFICA T DEPRESSIVE NEUROSIS...

For Brief Summary, please see following page.

SANDOZ
75-379

RESULTS OFTEN SEEN IN A WEEK

Because the somatic and psychic complaints that accompany depressive neurosis can interfere with the treatment of the underlying psychopathology—rapid relief of these symptoms is often crucial to therapy.

In 14 double-blind studies of four weeks duration, 339 patients with depressive neurosis received Mellaril. In these studies, 55% of the overall improvement was observed by the end of the first week, and a total of 293 patients (86%) improved during the four weeks.*

Mellaril usually does not cause euphoria or undue sedation and is nonaddicting. Patients, therefore, generally remain alert and better able to respond to therapy. (The physician should, however, caution patients against participating in activities which require complete mental alertness, e.g., driving.)

*Data on file at Sandoz Pharmaceuticals.

MELLARIL® (THIORIDAZINE)

TABLETS: 25 mg and 50 mg thioridazine HCl, U.S.P.

for the short-term treatment of moderate to marked depression with variable degrees of anxiety in patients with depressive neurosis

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg. should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling. The following reactions have occurred with phenothiazines and should be considered: *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient. In adults with depressive neurosis the usual starting dosage is 25 mg t.i.d. and the dosage ranges from 10 mg b.i.d. to q.i.d. in milder cases to 50 mg t.i.d. or q.i.d. for more severely disturbed patients; the total daily dose ranges from 20 mg to a maximum of 200 mg.

al and with medical ethics in particular. It seems to us that secular philosophers mostly raise questions, which is useful, but have no answers, while the theologians offer answers but not necessarily the right ones. Regardless of such reservations we recommend to anyone more seriously interested in ethics an introductory text such as Frankena's *Ethics* (12).

The most important recent publication in philosophical ethics, in our opinion, is Rawls's *A Theory of Justice* (13). It has many implications for the ethics of a health system. Rawls examined the concept of social justice designed to enhance fairness. To maximize liberty and to provide equal access to necessary services and commodities is the essential message of his text, which, as we stated before, is embodied in the right-to-health concept.

Another important contribution is Ramsey's analyses of medical ethics (14, 15), in which he defined ethical principles of behavior on the basis of the biblical concept of "covenant," which he saw as existing between physician and patient to maintain the "sanctity of life." Ramsey, a theologian, stated in his book *The Patient as Person* (15) that "caring," or "respect for human life," is the basic moral obligation binding individual medical decisions and the rules of medical practice.

Joseph Fletcher (16), a so-called situational ethicist, appealed to the medical profession through his pragmatism. We are also impressed with Clouser's attempts (17–19) to help physicians clarify their thinking about these issues.

Social and Behavioral Scientists

Important and extensive contributions to the field of medical and psychiatric ethics have been made by social and behavioral scientists. Their concerns are what values *are* rather than what they ought to be, what rules exist, how they are followed or not followed, and how they develop. In general, their point of view is closer to what psychiatrists espouse and can understand. We strongly believe that further important contributions will be made by behavioral and social scientists, particularly by economists, who are concerned primarily with what Dewey (20) called "instrumental values"—the vast array of technological tools and products—rather than with ideological values. Of course, the implementation of many ideological values depends on production, consumption, and priorities. Certainly this applies to medicine and psychiatry as well as to economics.

Psychoanalysts

One particular group that has explored values in depth is psychoanalysts, who have contributed major insights into preconscious and unconscious values. Sigmund Freud's concepts of the superego and the ego ideal (21) have been important and influential and have been taken over by dynamic psychiatry. Psychoanalysis has shaken older thought about rationality and free will—mainly through the introduction of the concept of unconscious conflict. In general, psychoanalysts, such as Hartmann (22) and Marcuse (23), maintain that psychoanalysis does not espouse any particular value system. This idea is not shared by all psychoanalysts, however. Fromm (24), Redlich (25), LaPiere (26), and others have stated that psychoanalysis has definite values and affinities to the values of certain cultures. It seems to flourish only in societies characterized by relative political and social freedom and is essentially elitist.

Lawyers

Finally, we would like to mention lawyers as a most influential group in the field of ethics, although they are not directly concerned with ethical issues unless controversy over such issues reaches courts of law. They certainly do not deal with trifling matters (*de minimis lex non curat*), but most of the major issues and problems in medical and psychiatric ethics sooner or later reach the courts, to be decided in ways that have a great deal of influence over the conduct of medicine and psychiatry. Examples are the decisions of Judges Bazelon and Johnson, which we will discuss further under the heading of the right to be treated.

Because most legislators are lawyers, legislation is another arena in which the legal profession exercises the greatest influence over policy in general and over medical and psychiatric policy in particular. We also want to point out that many consumer representatives and advocates are lawyers. The legal profession has clearly aided the civil rights movement in its defense of the rights and privileges of the committed patient. Some basic ideas on liberty and therapy and the civil implications of the "therapeutic state" have been expressed in the excellent book *The Right To Be Different* by Kittrie (27), who is a legal scholar.

From the preceding discussion it can be ascertained that defining the ethics of medicine and psychiatry today should be an interdisciplinary effort involving interdisciplinary societies and institutes. Scholarly work goes on in universities and in such free-standing institutes as the Hastings Institute of Society, Ethics, and the Life Sciences in Hastings-on-Hudson, N.Y., and the Society and Institute of Health and Human Values in Philadelphia, Pa. Publications of real interest to psychiatry are contained in the reports of the Hastings group, which has published the most comprehensive bibliography on medicine and bioethics to date (28); this bibliography includes a section on psychiatry.

THE RIGHT TO BE TREATED

The right to be treated has become a major and complicated legal issue. The right to treat is of equal complexity. We will not go into the legal complexities of these issues here, except to mention some important legal decisions that as precedents for further decisions will gradually establish some very definite rights of patients. We consider the right-to-be-treated issue far

more than a legal fiction. The array of legal and political problems involved in this issue has been masterfully described and analyzed by Stone (29).

The first major decision affecting this issue was made by Judge Bazelon (30), who ruled in *Rouse v. Cameron* (31) that a criminally insane patient who was committed to a mental hospital had the statutory right to be treated. Bazelon led the way for other landmark decisions by basing his ruling on the arguments of cruel and unusual punishment and the right to due process.

The second decision affecting the issue of the right to be treated was the ruling by Judge Johnson in *Wyatt v. Stickney* (32) that the State of Alabama must provide certain minimal standards of care in its mental hospitals or discharge its committed patients and that the state must appropriate funds for standards that the judge specified. This decision was appealed on the grounds of comity, or conflict between judicial and legislative discretion, and was initially not favored by the psychiatric establishment, which maintained that only a psychiatrist can define psychiatric standards.

The third decision involving the right to be treated was *Donaldson v. O'Connor* (33, 34), in which a paranoid patient who had been hospitalized for 14 years without treatment sued the physicians of the hospital for damages and demanded his discharge. When this case reached the Supreme Court it was ruled that patients who are not dangerous cannot be confined in institutions against their will if they do not receive treatment and if they could survive outside the institution with the help of friends or relatives. The court did not rule on the broader issue of whether all patients in a mental hospital have a right to treatment. The Supreme Court has not yet decided what the legal criteria for commitment are, nor has it upheld the *Wyatt v. Stickney* decision defining minimum standards for psychiatric care.

In another major case, *Robinson et al v. Weinberger et al*, which is pending, the Mental Health Law Project of Washington, D.C., asked a federal judge to order the District of Columbia to create adequate facilities in the community to permit the discharge of patients who do not receive adequate treatment from a state hospital—in this particular case St. Elizabeths Hospital, one of the nation's best. This case goes farther than the others because it does not merely suggest that patients should be "dumped." The ethical gist of the matter is that those few patients who therapeutically need to be confined should be treated adequately in institutions. Patients who are either not to be admitted or are to be discharged and treated in the community should be taken care of under proper conditions created for adequate care. In principle this goal is simple; in reality, due to the conflicting interests of patients, therapists, legislators, and lawyers, the problem is very complex.

Patients do not always want treatment; therapists want to treat, but only under conditions prescribed by them; and legislators may want to provide treatment but may not want to or are not able to provide funds for such purposes. These inequities have already produced some interesting legal opinions; more are undoubtedly to come.

Regrettably, the psychiatric establishment has assumed a conservative and defensive stance in these matters. First, it was not the psychiatrists but civil libertarian lawyers who pressed for changes. This created—to say the least—embarrassment and resistance among psychiatrists who worked in institutions; psychiatrists not associated with institutions still managed to maintain a detached apathy. Stone (29) strongly pleaded for more enlightened attitudes among psychiatrists, even for more enlightened self-interest. Legal precedents are leaning toward the legal and moral responsibility of the individual psychiatrist for the adequacy of treatment in public mental institutions. Legal suits have moved in the direction of holding individual psychiatrists responsible for the inadequate treatment in the public institutions they serve. Ultimately, of course, it is the patient's interest and not the expert's that needs to be considered and safeguarded.

THE RIGHT NOT TO BE TREATED

In general medicine and surgery in the United States today no competent adult patient can be treated without his informed consent. The parents' or guardians' consent is required for children; for adolescents the decisions are legally in the hands of parents or guardians, but, de facto, adolescents make their own decisions in most cases. Only psychiatric and mentally defective patients committed to institutions are (in most cases) denied this right (35). This means not only that they cannot make decisions about medical and surgical procedures, but also that they are forced to submit to them if this is deemed desirable by their physicians or the administrative head of the institution. They are not permitted to decide on their own whether they will be subjected to such serious and stressful procedures as ECT, insulin coma treatment, prolonged major psychopharmacological therapy, or psychosurgical procedures and conditioning treatment to modify behavior. Another procedure that all too often has been carried out without the patient's consent is sterilization. The restriction of the rights of these patients is based simply on the premise that a patient who has been committed to a psychiatric institution does not know what is best for him.

We contend that mental illness and commitment are not sufficient conditions for the restriction of the right to informed consent. To take away this right requires that evidence be presented in a court of law that the patient is incompetent. Of course, there is room for explanation and persuasion to induce a patient to consent to a medical, surgical, or psychiatric procedure that is in his interest, but there is no room for coercion and brainwashing. If a patient who is not declared incompetent does not want to be subjected to any particular treatment his judgment ought to be honored, even

if it is in disagreement with a clinician's judgment.

The right not to be treated was upheld in a federal court in *Winters v. Miller* (36). In reality, even voluntary patients in psychiatric hospitals are often subjected to strong pressures to accept treatment—a practice that we find objectionable from an ethical point of view even though the clinician's intent is benevolent. We know of patients who have consented to ECT and then—after being subjected to this severe treatment—have reversed their consent, but whose psychiatrists insisted that consent could not be reversed and treatment had to continue. We believe that this is wrong and that patients have the right to withdraw their consent at any time. In general, we feel that modern psychiatrists should be wary of taking on a parental and authoritarian function.

One important point, brought to our attention by Hardin Branch, is that if patients have the right to refuse treatment, individual psychiatrists as well as the profession of psychiatry must not be held responsible for social evils that may be the consequences of such refusal. Drunken drivers may refuse treatment by psychiatrists or by such peer groups as Alcoholics Anonymous; it is then up to society to devise other forms of control. It might be said that the control of deviance—largely forced upon psychiatry by society—is more of a curse than a boon to our profession and that we should be happy to leave it in the hands of the law for enforcement.

Halleck (37) discussed the following conditions under which coercive psychiatric treatment is justified: the patient must be dangerous to himself or to others, there must be reasonable probability that treatment will be beneficial to the patient or to others, and the patient must be incompetent to judge the effect of treatment. We agree, but we would go farther. Coercive treatment due to a patient's being dangerous or incompetent must be ordered by a court of law on the basis of evidence of such behavior and the value and availability of the treatment. In addition, treatment that benefits primarily others (presumably Halleck meant family, peers, or the community at large) should be conducted only if a court rules it. Actually, we cannot think of any good examples of such treatment unless it also benefits the patient.

One difficult problem is posed by patients who are dangerous to themselves. The question is, What is danger to oneself, what is self-destructiveness? We are not discussing minor patterns of behavior that are not in the patient's interest, but clearly suicidal behavior. The acutely suicidal patient may require prompt treatment that he does not wish to receive, although we recognize that there are normal persons who make a clear and cool decision to end their lives and who, in our opinion (though not in the opinion of many others), have a right to make such a decision. We know, however, that many severely depressed patients will not repeat suicide attempts once they are cured of their depression. In these cases a specific type of incompetence is involved. The judgment of such incompetence should be made by a court of law, if possible; we realize, however, that there are cases in which the legal approach would not be expedient and immediate action by psychiatrists is necessary.

RIGHTS OF PSYCHIATRIC PATIENTS

In general, the concept of informed consent has become the most important, most complex, and most confused concept in medical ethics. It essentially delineates or should delineate the patient's right to determine what kind of health-related procedures health personnel may or may not carry out. Many authors (15, pp 1–58; 38) also see this as the basic moral relationship underscoring all patient-physician contracts for medical treatment and human investigation. We believe that major changes regarding the rights of psychiatric patients that are comparable to the growing impact of effective psychopharmacology and the widening influence of psychotherapy on fairly large segments of the population are in the making. We do not wish to say, however, that a successful "rights" revolution has occurred. Many of our large public hospitals for chronic patients are still total institutions in the sense that they make all the decisions for patients in their care, even though on paper at least the general rights of patients have been spelled out.

With some shame we state that most of the changes in establishing patients' rights were not brought about primarily by psychiatrists but by civil libertarians led by lawyers, and that the most important decisions were made by enlightened judges. Of course, there have been superintendents of state hospitals who fought for more humane conditions in their institutions; concerned groups of psychiatrists; and, to mention one man in particular, the occasionally maligned Szasz, who unfortunately all too often has expressed good views in an unacceptable form.

Psychiatrists reject the idea that they are self-serving or that they are preserving an undesirable status quo. Indeed, we believe psychiatrists honestly think that in many cases compulsory treatment is more important for a given patient than his freedom. Psychiatrists in general opt for medical informality rather than for legal formality and for flexible medical therapeutic action rather than bureaucratic and legal surveillance. However, the tide of change has been in the direction of protecting the liberty of patients and also in the direction of growing legal and bureaucratic restrictions of the scope of psychiatric care. We will discuss the ethical but not the legal aspects of general rights of patients, commitment procedures, and the right to be treated and the right not to be treated.

General Rights

The changes in establishing patients' rights are to a certain extent expressed in statutes and regulations of the various state departments of mental health. These concern what one might call general rights of

patients (38)—such civil rights as the right to vote and to contract to hold or convey property. Only mental incompetence that has been proved and recognized by a court of law—not to be confused with the broader and different category of mental illness—ought to be a cause for the abrogation of these rights of patients in psychiatric institutions. It is specifically recognized that to deprive a patient of his belongings is apt to injure the patient's right to respect and dignity. Patients in mental institutions have the right to receive and send uncensored mail and to make and receive telephone calls, unless there are specific reasons—to be stated in writing by the administration of the institution—that make these privileges unwarranted for the patient or for society at large. Specifically, patients can be restrained or placed in seclusion only if they are dangerous to themselves or to others, and such restraints can be issued only with the consent of the chief administrator of the institution and must be constantly monitored and justified.

It is generally agreed that physical and chemical restraints ought to be used rarely and under no circumstances should they be used punitively. Another major ethical area of concern is the obligation to reduce the stigma of mental illness and, more specifically, to increase the patients' chances for fair employment and social interactions. Obviously, this is more easily said than done. In general, of course, we recognize that no legal or administrative provisions for these actions exist in many states and that even if they do exist they are not enforced or are circumvented.

Commitment Procedures

The most important right of the institutionalized patient is his basic right to the maximal degree of liberty that is compatible with his welfare and with the interests of society. Possible conflict between the individual's rights and the rights of society pose the most difficult problems in questions of treatment and research. These problems are particularly sensitive when the patients or subjects come from deprived or disenfranchised populations, e.g., psychotic patients, the mentally retarded, prisoners, and children. Much more careful work must be done before general ethical guidelines can be established.

These matters are regulated in all states by statutes defining various patterns of entry and discharge from institutions. In general we have observed in the last decade a very marked tendency to reduce the number of court commitments of psychiatric patients and to replace them with emergency and voluntary admissions. There has also been a tendency to discharge patients after a short period of hospitalization rather than keep them indefinitely. Psychiatrists generally do not like formal commitments. They consider it traumatic for most patients to be exposed to the stress of formal notice, representation by counsel, and cross-examination in court. They prefer the more informal emergency commitment.

In fact, psychiatrists feel threatened by legal challenges to their professional decisions. A recent study (39) suggested that this "professional" anxiety leads to poor clinical care: when psychiatric commitments were challenged by lawyers on behalf of their patient-clients in a public hospital in New York City there was a marked tendency for these patients to be discharged without a court appearance. This occurred in spite of the fact that the judges tended to universally support psychiatric decisions and the fact that the discharged patients were at least as sick as patients whose commitments were unchallenged and who remained hospitalized.

Libertarian lawyers are opposed to informal procedures, which in reality deprive the patient of his freedom, specifically his civil rights, without due process of law. Even so-called voluntary admissions, which have become the dominant mode of admission in many cases, "trap" the patient in a mental hospital because he is often not permitted to leave without giving written notice. One should realize, however, that it is not easy for a patient to leave a general hospital once he takes his shoes off; this is true even in shoe stores.

The only reason for formal commitment—and in our opinion for so-called emergency commitment as well—is danger to the patient or to others. Civil libertarian lawyers maintain that the need for treatment is not a sufficient reason for emergency commitment, a point of view that is not accepted by an appreciable number of psychiatrists. These lawyers also point out that it is difficult to predict dangerous behavior and that in the statutes of all states—with the exception of California, Massachusetts, and Maryland—the definitions of "danger" are very vague. One of the most difficult situations arises when a decision must be made to hospitalize a potentially suicidal patient against his will and to determine what type of admission he needs. As we mentioned before, we believe that suicide by patients with psychotic depression—presumably a true disease of unknown and complex etiology—ought to be prevented. Rapid commitment for these patients is essential, and therefore admission based on emergency certificate is not only clinically but ethically justified for them. The libertarian and clinical points of view are pitted against each other in two interesting articles, one by McGarry and Greenblatt (40) and one by Szasz (41). On the whole, we consider the present trend to be toward truly voluntary admissions.

During the last few years psychiatrists in the Western democracies have sharply criticized alleged psychiatric practices in the Soviet Union, where it is alleged that persons with politically undesirable actions and opinions who are not suffering from mental illness have been confined against their will in mental hospitals. Soviet psychiatrists have denied these charges. If they are true—and there seems to be some truth to these stories—this is a horrible abuse of the physician's powers and duties. As Judge Bazelon (42) and others (43) have pointed out, however, it is even more horrifying that large numbers of patients in the United States and in other democratic countries are deposited

in custodial welfare institutions, not because they suffer from mental illnesses, but because they are unwanted by their communities.

BEHAVIOR CONTROL

The problem of informed consent can be formulated as two questions: Who agrees to a decision? and Who decides what for whom? These questions are particularly pertinent for treatments that involve behavior control. According to London (44), who wrote an illuminating book on this topic, behavior control may be defined as attempts to influence persons to do somebody's bidding. It is a topic much broader than psychiatric therapy and includes vast segments of political propaganda, commercial advertising, moral and religious education, and rehabilitation of deviant persons.

The main problem in psychiatric behavior control is to delineate who has the right to set goals and approve methods and to safeguard those who do not wish to change their behavior or those who are not aware of what happens to them in the process. As methods of behavior change and behavior control become more efficient the problem is exacerbated. The reaction of concerned citizens inside and outside the profession of psychiatry to psychiatric methods of behavior control is strong, especially regarding those methods of behavior control which produce drastic, irreversible, and even dehumanizing changes.

The main categories of behavior change are the psychotherapies, the pharmacological therapies, the psychosurgical therapies, and the methods of genetic engineering. The impact of each of these methods is markedly different from the other because they vary in their capability to produce desired changes, their production of undesirable effects, their ease of application, their irreversibility, and the patient's awareness of their effects. Most important is the question of whether or not the patient is in a situation to give informed consent. That the patient should be protected from outright coercion may be a readily accepted idea and may be formalized in statutes and regulations, but that he should be protected from subtle pressures is a far more difficult idea to accept and to regulate. We know that individuals can be "brainwashed" to accept ideologies that a political regime considers desirable. The same is conceivable as far as psychiatric treatment is concerned.

Psychotherapy

The problems of behavior control vary with the different methods of therapy. Insight-producing psychotherapy as a method of behavior control incurs relatively few risks. The method is slow and limited to a relatively small target population. When behavior changes are produced the accompanying increased awareness enables the patient to monitor the behavior changes, at least to some degree. The more persuasive psychotherapy becomes, the less likely is such monitoring.

In conditioning psychotherapeutic methods the patient is less able to check undesirable changes and side effects. The gruesome movie *A Clockwork Orange* showed how an extremely aggressive asocial teenager turned for a while into a passive and helpless person. The danger of creating dehumanizing effects in a patient who has not given truly informed consent is a serious ethical breach, especially if the target symptom is undesirable political behavior and the technique is aimed to produce mind control. As far as we know this has not happened, but conceivably it could happen.

Pharmacotherapy

The risk of dehumanization is potentially even greater in behavior change produced by drugs. At present the power to change behavior by means of drugs is limited because the drugs used are relatively inefficient (although by no means harmless). To overtranquilize a patient is certainly to threaten his human freedom and dignity, apart from the danger of incurring the serious side effects that all tranquilizers produce. There is good reason for concern for the future, when there will be more powerful drugs with specific effects. At present our society is involved in exercising strict control over all drugs that are potentially harmful. Such control, particularly over the pleasure-producing drugs, is difficult and can be maintained only at high economic and social cost, as the addiction problem in many countries demonstrates.

Psychosurgery

The gravest concerns have been expressed over the use of psychosurgical techniques to produce behavior changes. The reason for this apprehension is the irreversibility of the changes produced by neurosurgical lesions and the patient's inability to protect himself against the consequences of such lesions once they have been produced. This is equally as true for the crude lobotomies that were carried out on a large scale in the 1940s and 1950s, which had definite dehumanizing effects in addition to their therapeutic results, as for today's refined microsurgical techniques. The fact that it takes highly skilled personnel to carry out such operations keeps the number of patients at risk relatively small; however, there is no statistical justification for harmful and unethical procedures.

Genetic Engineering

We also want to mention eugenic measures or methods of genetic engineering to alter human behavior (45). Since the disastrous and inhuman involuntary sterilizations that occurred under National Socialist rule in Germany, no serious scientist—except the physicist and Nobel prize laureate Shockley—has endorsed compulsory eugenic sterilization. There has been some discussion (46–48) about future approaches, such as cloning, to improve the human race. How-

ever, this is one problem that today's psychiatrists need not worry about yet.

A policy position of the National Institute of Mental Health on this subject (49) highlighted the wide and increasing use of behavior modification, including behavior change by drugs and neurosurgical techniques. At present, according to this publication, 600,000 persons receive such treatment. NIMH recognized the value of behavior modification but cautioned therapists and patients that therapists are accountable to patients and their representatives for the effects of such treatment; they must weigh the risks and benefits and inform the patients about the effects. This is particularly important if patients are in mental hospitals, if they are senile, or if they are prisoners because the imbalance of power between these patients and their therapists warrants particular caution and careful monitoring.

CONFLICTS OF INTEREST IN THERAPEUTIC GOALS

The right to be treated or not to be treated, in general, and the right to agree to or to decline behavior modification treatment, in particular, often raise questions of conflicts of interest. Does the therapist satisfy the interest of the patient or his own interest? To a certain extent the therapist always satisfies his own interests to make a living, to gain prestige, to fulfill his moral need to help, or to increase his knowledge; within certain limits this is entirely permissible and desirable. However, in many situations the therapist serves a third party, particularly when he is an employee of an institution whose interests are not necessarily identical to the interests of the patient. Third-party interest can also occur in solo private practice when a third party requests the treatment or pays for it. This third party may then overtly or covertly, grossly or subtly, influence the psychiatrist to do his bidding. This is often the case when children or adolescents are in treatment or when a patient's spouse pays for therapy. It also happens when persons on whom the psychiatrist depends, or to whom he is or wishes to be obligated, influence treatment goals. The most malignant of these instances concern the individuals who are imprisoned in psychiatric institutions for political reasons (9). We believe that subtle forms of pressure by third parties are applied often and everywhere—not only under dictatorships. We are also convinced that psychiatrists are not sufficiently aware of these pressures.

Conflict of interest is one facet of the wider problem of what values, especially what conflicting values, are served by psychiatry and how the values of therapists, patients, third parties, and society at large may differ markedly from one another. The problems, particularly in prisons or in relatively monolithic organizations such as the armed forces, may be insoluble. What we plead for is greater awareness of these value conflicts. Unfortunately, psychiatrists have a marked tendency to assume that they operate in a valueless frame of reference; although they keenly notice their patients' conflicts, they are less inclined to see their own. The psychiatrist, no matter what his theoretical orientation, is almost always a party to conflict, and he needs to be aware of this (50).

PRIVACY AND CONFIDENTIALITY

Privacy is a pervasive ethical concept with wide personal, political, and legal implications. It is of central importance for psychiatry. Greenawalt (51) defined it as the right to be left alone. To exclude the public to a certain extent is one of the great values of the free world, according to Westin (52). Privacy refers to the control of the flow of information about a person to others, to the invasion of one's private sphere (one's home and possessions—as in searches and wiretapping), and to the right within limits to live according to one's own wishes. These concerns, particularly the intrusion into and public revelation of a person's inner world (his conscious and preconscious thoughts, feelings, and volitions), are extremely important in psychiatric treatment. One important aspect of this larger issue of privacy, with the implied right of the patient to accept or reject treatment, is the narrower issue of confidentiality.

Private Practice

The concept of professional confidentiality refers to the obligation of certain professions to respect information revealed in professional activities. Professional secrecy in medicine is mentioned in the Hippocratic Oath. It is protected in many states and countries by privileged testimony in courts of law in recognition of the fact that information obtained in the relationship of physicians and their patients is particularly sensitive and may lead to serious occupational and social damage if revealed in public.

Again, in this article we are not concerned with the legal complexities of privacy and confidentiality but with basic ethical considerations. Are there situations in which confidentiality ought to be relaxed in the interest of the patient or in the interest of others and society at large? Benefits, risks, and potential harm must be balanced against each other, and no general valid ethical guidance can be offered, although most frequently psychiatrists will act according to what they consider to be in the best interest of the patient.

The problems of confidentiality are highlighted in the "warning" case of *Tarasoff v. Regents*, which is pending in California. This case involves a therapist who revealed the possible risk of homicidal behavior in a dangerous patient to the police, who could not act upon this information, but not to the victim, who was later killed by the patient. The psychotherapist and the police were subsequently sued by the family of the victim. Although this case is unresolved, the current tendency of the courts is not to make public disclosure of confidential patient information mandatory. This legal situation intensifies the ethical dilemma for the psychi-

atrist in this type of case, in which the welfare of society is clearly balanced against personal privacy. This is an area in which professional ethics must provide the ultimate guidance and in which the best interest of the patient as an ethical touchstone comes under the greatest strain.

Psychiatric Research

Both privacy and confidentiality are invariably tested in the context of psychiatric research. In most types of clinical psychiatric and psychological research as well as in standard clinical observation the patient is subjected to more or less intensive and extensive exploration of his personality and social relations. Even when this is done with the patient's explicit consent, he is hardly ever aware of the depth and meaning of such explorations—especially in more thorough investigations. If this is done in the interest of the patient (as it is in most therapeutic encounters), no conflict will arise. If the revelations are used for research and publication, even with the explicit consent of the patient, there may be ethical problems, such as there were in the case of *Doe v. Roe*, which was recently returned undecided to a lower court by the Supreme Court.

Investigators and clinicians who report their data in journals and at teaching conferences try to conceal the identity of their patients. Usually these disguises are rather ineffective, especially today when the "nonreading" charity patient—on whom much of the research has been done in the past—has virtually disappeared. It is much more likely today that psychiatric patients will read full accounts or vignettes of their case histories. The patient may find it difficult to accept the published findings of the investigator, or he may find the conclusions outright damaging and then sue, especially if he feels hostile toward the psychiatrist.

Group and Couples Therapy

The problem of confidentiality is particularly sticky in group and couples therapy. Patients are under no professional ethical obligations of confidentiality. Although the leader of a therapeutic group may stress the desirability of not discussing the content of the therapy outside the group, he cannot enforce this effectively. Members of groups ought to be at least apprised of this risk. In contrast to ex-President Nixon's practice, psychiatrists have learned to be scrupulous about obtaining permission to record by sound, videotape, or film. Such documents ought to be used with great care and tight security controls.

We would also like to refer to the type of breach of confidentiality that should be the easiest to control—professional gossip. It is our impression that many members of the mental health professions talk too loosely. Otto Pötzl once remarked that any psychiatric diagnosis is a form of slander and ought to be defended in court. Has the stigma of having a mental illness changed, except among a small group of intellectuals? Shouldn't we exercise more restraint?

Data Systems

There has been considerable concern over leakage of information through computerized data systems. With national health insurance and, perhaps, national health data systems just around the corner, this concern seems justified. Experts in the field, such as Westin (53) and Sawyer and Schechter (54), seem less worried about such dangers. Actually, the dangers already exist in traditional records. However, with appropriate legislation it would not be difficult to make these data sufficiently secure and to prevent unauthorized access to them. It is also of importance to destroy data that are not essential and to record only minimal data if they are likely to become public.

HUMAN EXPERIMENTATION

Ethical rules and statutes governing biological and psychosocial research have changed radically since the trials of the National Socialist experimenters accused of crimes against humanity. The general deliberations of the Nuremberg Court have become known as the Nuremberg Code. The rules and regulations that govern research in the United States have been patterned after the 10 points of that code and have had profound influence on attitudes toward biomedical and psychiatric research (55). All government-supported research in the United States must abide by these rules. In our opinion, these rules have greatly helped to protect the patient and have made investigators more sensitive to the experiences of their subjects, although, in the opinion of some, they also have had an inhibiting effect on human research.

Although the committees of medical centers scrutinize applications for research, they almost never monitor the ethical conduct of the research. Psychiatric patients, particularly institutionalized patients suffering from severe disorders, are more vulnerable than other medical and surgical patients. They require greater protection and special considerations in relation to investigative procedures. The three basic considerations are free and informed consent of the patient, the weighing of possible benefits and risks, and the avoidance of suffering and danger. Psychiatric patients who have been declared incompetent are not able to consent freely to research. Consent has to be given for them by relatives or guardians. Most concerned experts assume under these circumstances that research should be carried out only if it benefits the patient directly, if it holds promise that the patient might benefit in the foreseeable future, or if it benefits at least a group of patients suffering from an identical or closely related disease or disorder.

The informed consent rule also eliminates observations by concealed observers. Caudill's research in the early 1950s would not be approved under current rules (56): he stayed on a psychiatric ward under the pretense of being a patient. This holds also for the

more recent investigations of Rosenhan (57), who had a group of people enter a mental hospital as "fake" patients, even though his observations were of considerable value and could not be duplicated in their entirety by a regular participant-observer. The research of Milgram (58), who deliberately misinformed paid volunteers to test their capacity to obey cruel commands, would also not be allowed.

One particular problem in judging and balancing positive and negative effects of research is posed by research that investigates organizations and institutions. Consent for research is usually given by the leadership of an organization. The rank-and-file members of the organization are usually not given the chance to agree or disagree. Because one usually cannot predict the impact that the research will have on the organization or its members, the participants may have accepted research that proves to be highly critical of the organization and damaging to its members. Probably the best way to safeguard the interests of organizations and their members is to let them scrutinize scientific reports before publication. This will at least give them a chance to correct potentially damaging or insensitive statements. It will, on the other hand, curb freedom of research. Just as psychosocial research on underprivileged minorities in ghettos or on people in developing countries is critically reviewed before consent is given, psychosocial research in organizations and in the community should be subject to more stringent examination before it can take place.

THE ETHICS OF POLICY DECISIONS

We discern a definite trend in medical ethics to move from considerations of the physician-patient relationship to broader ethical considerations of policy decision making. The right-to-treatment problem and the regulations governing experimentation are pertinent examples. In general there was little broad and systematic policy planning outside the public mental hospital sector until World War II. Most of the planning until then had been haphazard, without clear formulations of goals, methods, or costs. During World War II and in the period following the war, when NIMH emerged, planning became quite deliberate.

From the very beginning NIMH established its main goals on the basis of a philosophy embodied in public health. These goals included broader and more equal access to mental health care and a program of prevention. The former was a laudable but difficult to implement goal because of its cost and a lack of manpower; the latter was utopian in the face of the amount of knowledge about preventing mental illness. There is little doubt that after a good start much of the community mental health movement has slowed down.

The point we wish to make is that certain ideological values guided the first professional planners in psychiatry. They knew that implementation of their goals would require vast economic resources, which were available only to a limited degree because the political leadership had other priorities than health and mental health. To persuade legislators to change their value priorities became a crucial task.

Possibly the most important clarification of psychiatry's ideological and technological values would be to define with the national leadership what the practical job of psychiatry is: to diagnose, treat, and prevent a relatively defined number of psychoses? to perform this task on a number of neurotics? to make unhappy and incompetent persons happy and competent? or to tackle poverty and civil and international strife? We are convinced that psychiatrists must beware of diffusion, collusion, and utopian endeavors and state their tasks in the form of clear priorities.

Today, on the eve of the initiation of a national health insurance program, one of the principal policy questions for psychiatry is to what extent psychiatric services, training, and research will be paid for and who gets paid for them. Undoubtedly this will be of the greatest importance for patients and practitioners alike (59). APA is keenly aware of this and is trying to persuade the nation's legislative and administrative leadership to enact proper legislation and allocation of funds. The arguments for such steps are largely ethical in terms of the needs of suffering populations and in terms of fairness and justice.

PSYCHIATRY AND CHANGING MORAL VALUES

Professional persons, including psychiatrists, do not make moral rules or change them. They accept or reject the rules of their culture and interpret them for themselves and their patients. In a pluralistic society this is a complex and often confusing process. Psychiatrists vary widely in their own moral views, as Rogow (60) has shown. Some are unusually flexible and permissive; others are remarkably authoritarian and paternalistic. We mentioned the current general trend in industrialized democracies to decrease authority and to interpret ends and means pluralistically (61). We have also referred to many aspects of a new balance between consumer power and professional power —the former is increasing and the latter is decreasing. Underprivileged minorities, particularly blacks and Spanish-speaking Americans, have gained much in status and rights. Women have moved toward socioeconomic equality. These changes in attitude are paralleled by a trend toward equality of opportunity for psychiatric treatment.

There have been marked changes in the prevalent morals in North America since the immediate post-World War II period. The attitudes toward self-destructive acts and victimless crimes have become more relaxed and less punitive. In psychiatry these changes in attitude have affected alcoholics, who are now considered in need of control and treatment rather than punishment. Less change of opinion has taken

place in regard to users of other drugs (62); in general, society continues its vendetta against even harmless addiction. Some psychiatrists have feebly expressed their opposition to such repressive and punitive points of view, with little avail.

Remarkable changes of attitude have been taking place in the sexual mores of large segments of the population of the United States. Greater permissiveness concerning the varieties of sexuality and sexual behavior outside of marriage is obvious. Sexuality—including masturbation—is considered to be, in the words of Masters and Johnson, a natural act.

• After a referendum APA struck homosexuality from its diagnostic nomenclature and replaced it with the term "sexual orientation disturbance." Obviously, one can no more vote on what a disease is than one can vote on whether the moon is made of green cheese, but one can vote on rights and sanctions. The question is not whether homosexuals are sick or deviant but whether they ought to have the opportunity to work toward sexual change if they choose to and whether they ought to be punished and discriminated against. Most psychiatrists would agree that homosexuals ought to have the opportunity either to attempt to change or to adjust optimally to their condition. They also ought to be protected from socioeconomic discrimination and legal harassment. With some clearer ethical thinking, APA's embarrassing referendum could have been avoided.

COMMENT

There is one area in which a psychiatrist made a fundamental contribution to ethics: Freud's discovery and formulation of unconscious motivation and conflict. The question of the limits of free will and of responsibility were raised once more with Freud's discovery, and the complexity and confusion became greater than ever. According to most ethical doctrines, one cannot be responsible for one's unconscious acts. However, every act, whether unconscious or not, has antecedents and consequences. It is the primary task of psychiatry to study antecedents and consequences of behavior that we call abnormal and to apply methods of intervention to alter such behavior. In pursuing this task we will learn more about the limits of will and responsibility. If we do not expect quick solutions to confusing problems and pseudoproblems, we may be able to make our contribution to an age-old theoretical and practical question.

Current Trends in the Training of Family Therapists

BY EDWARD W. BEAL, M.D.

The author describes and compares training programs for family therapists at 15 centers in 9 major U.S. cities, using a scale that reflects the spectrum of theoretical approaches to family therapy. At one end of the spectrum are the centers with an experiential orientation, at the other end are those with a structural orientation, and in the middle are those which combine these orientations. He concludes that although creative theoretical advances are being made at a few of these centers, the quality and design of training at the remaining centers suffer from the absence of an adequate diagnostic nomenclature for family therapy and from an insufficiently designed conceptual framework.

THE DIVERSE NATURE of family therapy training programs is related to the evolution of the "family therapy movement" during the past 20 years. At the end of World War II psychiatry was dominated by a theory that was oriented toward the understanding of individual psychological functioning. The family of an individual in therapy was important only as it affected the relationship between the individual and the therapist. Collateral visits with family members were occasionally held, but these were not the focus of treatment.

The interest in group psychotherapy that emerged after World War II represented a major change in the theory and technique of understanding psychological functioning. Although the focus on the therapist-patient relationship was then diluted and the therapy process was shared by other group members, the family of the patient in group therapy still remained therapeutically in the background.

A significant technical change for the family therapy movement occurred with the birth of family group therapy, when the practice of conducting group psychotherapy with naturally occurring groups rather than with artificially composed groups began. This change was primarily technical rather than theoretical. Therapeutic intervention was then focused on the relationships among individuals related by family ties rather than on the relationships among individuals united by various categories of psychological functioning.

From these technical and theoretical changes has emerged a large body of information on group process that has been used by family therapists who focus on the group process within a family. Since 1960, multiple-family group therapy has emerged as a logical progression of the treatment of the individual family as a group (1).

As the theory of group process and its technical application to family groups has emerged, increasing efforts have been made by psychoanalytically oriented psychiatrists to study the relationship between an individual's psychological functioning and the environment of his family. A significant effort has been made to extend individual psychoanalytic theory toward an understanding of the individual in his relationships with his family.

Thus far in this paper the focus has been on those forms of family therapy in which the practice and techniques rather than the theory of family therapy distinguish family therapy from other therapeutic procedures. During the past 20 years, however, a major theoretical shift has occurred in which family therapy has become more a new theoretical orientation toward the understanding of emotional functioning and less a method or technique defined by the number of people in a room. This new theoretical understanding of emotional functioning and of family therapy has been influenced by communications theory, general systems theory, and family systems theory. Multiple-family group therapy, in this theoretical frame of reference, focuses on family emotional processes rather than on group process as the method of therapeutic intervention.

CLASSIFICATION OF FAMILY THERAPY THEORY

Any attempt to assess current trends in the training of family therapists must consider the significant differences in theoretical viewpoints and technical applications of family therapy between and within various training programs.

To compare the diverse theoretical viewpoints of family therapy training centers, I have used a modified form of a scale published by the Group for the Advancement of Psychiatry (2). This scale is designed to reflect the spectrum of theoretical approaches to the understanding and treatment of families. It demonstrates contrasting ways of understanding the ex-

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Beal is Clinical Instructor, Department of Psychiatry, Georgetown University Medical School, Washington, D.C., and Chief Child Psychiatrist, Community Psychiatric Clinic, Bethesda, Md. Address reprint requests to him at 8830 Cameron St., Suite 603, Silver Spring, Md. 20910.

pression of emotional tension or affect in a family. As one moves from the A to the Z end of the scale, less theoretical and technical emphasis is placed on the direct expression of affect and more on the structure of family relationships. The theory at the A end of the scale is categorized as more experientially oriented, the theory at the Z end as more structurally oriented, and the theory in the middle (M) as a combination of these two orientations. The experiential-versus-structural approach as a method of comparison has been increasingly used in the past few years. This method is one of many ways of evaluating the field of family therapy.

This study is designed to illustrate similarities and differences that exist among theoretical approaches and training programs. It is not designed to evaluate the superiority of one theory or therapeutic approach to another. My research has been based on the assumption that training methods and techniques follow logically from theoretical understanding. In addition to comparing these theoretical understandings, I attempted to answer the basic questions of who is being trained, by whom, what is being taught, where is it occurring, and how it is being accomplished.

I made no attempt to consider all of the family therapy training centers in the United States. Rather, I selected a cross section of 15 centers in 9 major cities on the basis of the prestige of individual teachers at these centers, the number of publications produced by authors from the centers, and the frequency with which symposiums, seminars, or workshops were offered. The information contained in this study was gathered through correspondence with directors of education of family therapy programs, innumerable personal conversations with trainees and teachers, many site visits, and the reading of training brochures.

The criteria I used in comparing the training centers included the following: theoretical orientation, supervisory methods, technical interventions, trainees, trainers, curriculum, location, and methodology.

CLASSIFICATION OF TRAINING CENTERS

A: Experiential Orientation

Centers that fall at the A end of the theoretical scale include the following: the Menninger School of Psychiatry, Topeka, Kans.; the Family Institute of Chicago, Ill.; the University of Wisconsin Medical School, Madison, Wisc.; the University of Colorado Medical School, Denver, Colo.; and the University of Minnesota Medical School, the Midwest Family Therapy Institute, and the Amherst H. Wilder Child Guidance Clinic in the Minneapolis-St. Paul, Minn., area.

The assumption of therapists at the A end of the scale is that relationships are significantly influenced by the expression or inhibition of affect or emotional tension. Direct expression of this tension or affect is therefore appropriate and indicated for the maintenance of healthy relationships in a family. Therapists at the A end of the scale use group psychotherapy theory and techniques. The modality for emotional growth is considered by these therapists to be the therapeutic relationship between therapist and patient. They emphasize the subjective experience of therapy and the subjective awareness and intuition of the therapist to guide the therapy. Some of these therapists conceptualize family therapy as a technique to facilitate individual psychotherapy. The A therapists also consider indications and contraindications for family therapy.

The process that is primarily studied by therapists at the A end of the scale is the one that exists among members of the family group in therapy and between each of them and the therapist. A variety of techniques is used within this framework, including family sculpting, psychodrama, Gestalt therapy, behavior modification, encounter group techniques, interpretation of unconscious conflicts, and group process techniques. Teaching methods at the centers named above include lectures, literature seminars, small group discussions, experiential techniques, and live and videotaped demonstrations of family interviews by faculty and students.

Teachers at these centers are more often from psychiatry and social work than from other disciplines. The trainees in the medical school programs are psychiatry and psychology residents, medical students, and practitioners from the community. The family therapy institutes tend to accept only postgraduate students for course work and supervision on a part-time basis. Supervision of trainees is frequently done through live or videotaped observation of the trainee's sessions with families or through group discussions; rarely does it involve the traditional one-to-one type.

Carl Whitaker, M.D., of the University of Wisconsin Medical School, is the most noted professional from any of the centers at the A end of the theoretical spectrum named above. Unlike some leaders in the family therapy movement, Whitaker is less theoretically oriented; his outstanding strength is his creative, intuitive, and personal approach to treatment. He has an intrusive but gentle style with families and assumes a variety of roles as a therapist. He also makes ingenious use of cotherapists. Trainees are fascinated by his technical skill, but many state that his style seems too unpredictable to be learned. Whitaker is particularly skillful in his use of extended family members, especially grandparents, whom he encourages to attend family sessions.

The training at the remaining centers is done by individuals who are practicing family therapists. These therapists teach from their own experience, by reviewing the appropriate literature, and by attending workshops. The quality and design of the training at these centers appears to suffer from the absence of an adequate diagnostic nomenclature for family therapy as well as from an insufficiently designed conceptual framework.

Z: Structural Orientation

Centers that fall at the Z end of the theoretical scale include the following: the Philadelphia Child Guidance Clinic in Pennsylvania and the Georgetown University Postgraduate Program in Family and Systems Theory and Family Psychotherapy and the Groome Child Guidance Center in Washington, D.C. The assumption of therapists at the Z end of the scale is that emotional tension leads to a process that manifests itself in the structure of family relationships. They believe that this tension is maintained or resolved by the nature of the communication pathways or the relationship system through which it is transmitted. Some Z therapists believe that changing communication pathways and feedback systems is the appropriate method of intervention in a dysfunctional family. Others believe that a family relationship system can be modified by changing the part an individual plays in the relationship system.

Group psychotherapy theory is seldom if ever used within the Z structural orientation. Indications and contraindications for family therapy are not considered to be relevant by Z therapists. The course of therapy is defined more by predetermined theory than by the therapist's subjective feelings. The Z therapists appear to be oriented more toward theory and research than toward therapy.

Major training efforts at these 3 centers are focused on professionals with advanced degrees, primarily in psychiatry and social work. The Philadelphia Child Guidance Clinic and the Georgetown program also place significant emphasis on the training of residents in psychiatry and interns in psychology as well as medical students. The Philadelphia clinic has designed and implemented a unique 40-hour-a-week, two-year family therapy training program for nonprofessional high school graduates who have lived in the area serviced by the clinic.

The primary teachers at Georgetown and at the Philadelphia Child Guidance Clinic, Murray Bowen, M.D., and Salvador Minuchen, M.D., respectively, have extensive psychoanalytic training. However, they deny the value of this theoretical framework for their functioning as family therapists. Minuchen and Bowen clearly identify themselves with the structurally oriented Z therapists, but each has developed different concepts of family theory and structure and different technical interventions and training methods. Their different training methods appear to follow logically from their respective theoretical premises.

Minuchen (3) defines the structure of the family by the patterns of coalitions and splits among family members. These are reflected in the communication pathways that family members follow. A primary objective of Minuchen's structural family therapy orientation is to modify the existing patterns of family coalitions, splits, and communication pathways (4). One of the most characteristic technical features of this orientation, according to Camp (4), "is the deliberate employment of commands, directions, and suggestions as the therapist takes self-conscious responsibility for the direction in which he is pushing the family." This technical approach is specifically designed to modify the feedback system reflected in the communication pathways of the relationship system of the family.

Supervision and training methods at the Philadelphia Child Guidance Clinic are logically designed to make the therapist aware of the feedback mechanisms through which family members organize communication. Therapists in training have feedback mechanisms from their supervisors built into the very architecture of the therapy rooms, which are equipped with one-way mirrors, one-way sound, a telephone line between observation room and interviewing room, and appropriate videotape facilities. This equipment allows constant or periodic monitoring of the therapist-family communication pathways by the supervisor. Immediate consultation can be initiated by either supervisor or therapist; this allows the therapist to readjust his approach to the feedback system within the family.

The Philadelphia Child Guidance Clinic offers family therapy training for individuals who have already been trained in a mental health profession. Periodic workshops focused on specific issues are offered for mental health professionals who are not employed by the clinic. New staff at the clinic are taught by Dr. Minuchen in a two-hour seminar once a week. Additional supervision and observation for up to about five hours a week are provided during family therapy when necessary. Each successive year a junior staff member receives less supervision; after three to four years he is free to work on his own.

Although both Bowen and Minuchen are at the Z or structural end of the scale, their theories, therapeutic interventions, and training methods are markedly different. One of the cornerstones of Bowen's theory is the concept of differentiation of self, which is a measure of the degree of fusion between the intellectual and the emotional systems within an individual. It is also a measure of the degree of unresolved emotional attachment between an individual and his parent. Bowen believes that this emotional and intellectual fusion within the individual and between an individual and his parents manifests itself in the manner in which the individual functions in the relationship system in his nuclear or extended family. He also believes that this pattern of fusion in the family relationship system is so predictable that it can be traced through generations.

According to Bowen, the range of relationship patterns in the system between parents and children is as follows: 1) marital conflict, 2) physical, emotional, or social dysfunction in one spouse, 3) projection of parental problems onto one or more of the children, or 4) a combination of all three patterns. The way these patterns are processed is explained by Bowen's concept of the triangle. His theory assumes that a two-person system is basically unstable and that in an emotional field two people involve a third to make a triangle in an attempt to resolve the tension. This concept describes

the way any three people relate to each other and involve others in the emotional issues among them. The predictable moves in the triangle have been used to develop a system of therapy designed to modify the triangular emotional system.

Therapy within this framework focuses on the most important triangles in the family. It is designed to help one or more family members to become aware of and modify their emotional responsiveness to triangular moves by other family members. Bowen's therapy is basically designed to modify the family relationship system by modifying the part an individual plays in the triangles of the family emotional system. He clearly distinguishes himself from other family theorists by attempting to remain in contact with but outside of the family emotional system.

According to Bowen,

> When one person in the triangle can control self while still remaining in emotional contact with the other two, the emotional tension between the other two subsides. When it is possible to modify the central triangle in a family, the other family triangles are automatically modified without involving other family members in therapy. (5, p.382)

Bowen's therapeutic method is clearly designed to place "the two most important family members [parents] into therapy with the therapist, which makes the therapist the target for family efforts to involve a third person" (5, p.385). Progress in therapy depends on the therapist's ability to maintain meaningful contact with but remain outside of the emotional processes operating among family members. Bowen encourages family members to make contact with as many members as possible of their extended family system to learn more about the emotional processes passed down to them.

Bowen's teaching places strong emphasis on theory and its technical application. Trainees are encouraged to understand their emotional functioning in their own family. Meeting for three hours a week, his postgraduate program has a general portion that stresses theory and technique and a research teaching portion. More advanced therapists meet with Dr. Bowen in other research and teaching conferences held each week. The length of either program is a function of the trainee's progress as a therapist and work in his own family system. The annual fall Georgetown symposium, now in its 11th year, is the major teaching and research event of the year. A two-year family fellowship for third- and fourth-year psychiatry residents began in 1975.

M: Combination of A and Z Orientations

The following institutes fall at the M position on the theoretical scale: the Boston Family Institute in Massachusetts; the Center for Family Learning, New Rochelle, N.Y.; the Bronx Psychiatric Center, Albert Einstein College of Medicine, New York, N.Y.; the Nathan W. Ackerman Family Institute, New York, N.Y.; and the Family Institute of Philadelphia, Pa. The type of family therapy practiced by the faculty at these centers has characteristics of both the A and Z ends of the spectrum. The orientation of individual faculty members at some of the centers falls more clearly at one or the other end of the scale. The overall theoretical orientation of these centers, however, is a mixture of family and individual concepts with a wide variety of techniques. Two factors that appear to influence an individual therapist's place on the scale are his motivation for theory and research and the geographical and professional environment in which he works.

The trainees at all of these institutions are fully trained mental health professionals. The Boston Family Institute also includes teachers, homemakers, and B.A. candidates among their trainees (6), and the Bronx Psychiatric Center includes undergraduates from the various mental health disciplines. The Center for Family Learning appears to be the only institution with an integrated program to make basic knowledge of family process and function available to the nonprofessional community.

The format for training at most of these institutions includes periodic and annual workshops with noted family therapists as well as year-long courses that may be held for two to four years. Supervision is frequently done through live or videotaped observation of the trainees' sessions with families or through discussions in small groups. Literature seminars are offered on the nature of the clinical interview, the study of family process, and in various theories of family therapy. Family therapy techniques used by the faculty at these institutions include psychodrama, Gestalt therapy, behavior modification, structural therapy, family reconstruction, group dynamics, network therapy, modeling, family sculpting, and multiple-family group therapy.

The therapists at some of these centers, especially the senior faculty of the Center for Family Learning, have moved toward the Z end of the theoretical spectrum with its emphasis on studying one's own functioning in one's nuclear and extended family system.

DISCUSSION

There are no central or comprehensive sources of information about family therapy training in the United States. Most training centers and many mental health professionals are unaware of what other centers are doing in their training programs. Although the Group for the Advancement of Psychiatry's report *The Field of Family Therapy* (2) dealt with conceptual approaches, treatment techniques, and the actual practice of family therapy, it did not address itself to the issue of training family therapists. In this study I have attempted to describe, assess, and compare a selected group of training programs.

Creative and innovative theoretical advances are being made at a few of these training centers. Disciples of these innovators are attempting to teach and in-

tegrate these varied concepts at other centers. However, the quality and the design of the training at most of the centers suffer from the absence of an adequate diagnostic nomenclature for family therapy as well as from an insufficiently designed conceptual framework.

Family institutes tend to be centers where multiple theoretical approaches are taught. Smaller clinics often follow the theoretical orientation of one creative individual. Supervision almost always involves live or videotaped observation of family therapy sessions or group discussions; rarely does it involve the more traditional one-to-one type. A few institutions are now beginning to heavily emphasize the idea that trainees need to study and understand their functioning in their own nuclear and extended families as well as develop a system orientation to life situations.

The introduction of family therapy training into psychiatric centers organized along traditional lines in which emphasis is placed on psychoanalysis and individual psychotherapy often creates disequilibrium and dysfunction. It takes the highest order of understanding and skill to achieve the integration of family therapy and training into these systems. This integration is one of the things the mental health profession hopes to accomplish in other kinds of systems that are dysfunctional, whether an individual, a family, a school, a company, or a community. It would be ironic if the mental health profession could not achieve some integration of family therapy with other modalities of treatment to the enrichment of all treatment methods.

Crime and Violence Among Mental Patients

BY ARTHUR ZITRIN, M.D., ANNE S. HARDESTY, PH.D., EUGENE I. BURDOCK, PH.D., AND ANN K. DROSSMAN

The authors studied the arrest rates of 867 patients from the Bellevue catchment area who were discharged from the psychiatric division of Bellevue Hospital. They found that the arrest rates of these patients for two years preceding and two years following their admissions to the study were higher than the arrest rates for the general population of the Bellevue catchment area as well as those for 4,601 cities in the United States. They discuss the implications of this finding for the postdischarge care of mental patients, particularly in the light of current discharge policies.

THERE HAS BEEN a marked reduction in the number of patients in mental hospitals in recent years (1, 2). In California the mental hospital census has dropped from about 30,000 to 7,000 over the past five years; in New York State the census has declined from 70,000 to 35,000 during the same period. This phenomenon and the enactment in some states of legislation that narrows the criteria for involuntary hospitalization of the mentally ill have focused the attention of psychiatrists and the public on the problems engendered by large numbers of former mental hospital patients in the community (3) and, in particular, on the relation between mental illness and criminal behavior (4).

The literature on crime and mental illness is sparse and contradictory. Studies done in 1922 (5), 1930 (6), and 1938 (6), which were based on New York State hospital statistics, reported lower arrest rates for discharged patients than for the general population. A study done in Connecticut in 1945 (7) agreed with the findings for New York. In the Connecticut study the arrest rate for felonies, calculated over a two-year period, was 4.2 per 1,000 for ex-patients and over 27 per 1,000 for the general population. Comparable results were found for misdemeanors.

An extensive study of a population of 10,247 male patients over the age of 16 who had been released from New York State hospitals between 1946 and 1948 was reported by Brill and Malzberg in 1962 (8). These authors obtained the arrest records for 5,354 of these patients for the whole period before discharge and for the five years after discharge and determined indirectly the arrest rates of the remainder (N=4,893) of their sample. They reported that the overall arrest rate for ex-patients was 122 per 10,000, while that for the general population was 491 per 10,000. However, they also found that the arrest rate for felonies was higher for the ex-patients than for the general population (54.70 per 10,000, compared with 32.83 per 10,000). The higher rate of arrests for felonies among the ex-patients, according to the authors, "was found to be due to the presence among the patients of a disproportionate number with a previous arrest record. Because of the universally high rate of arrest among the latter group, a small excess of their number has a strong influence on the total figure" (8).

In 1965, Rappeport and Lassen (9) reported their study of the arrest records for periods of five years before and five years after hospitalization of all male patients over the age of 16 who had been discharged from all psychiatric hospitals in Maryland during 1947 (N=708) and 1957 (N=2,152). Focusing only on arrests for serious crimes against persons (murder, negligent manslaughter, rape, robbery, and aggravated assault), they found that the arrest rate for robbery was significantly higher for both populations of ex-patients than for the general population. Arrest rates for the other crimes against persons were slightly higher for the ex-patients than for the general population. Schizophrenic patients accounted for more than 30% of the arrests before and after hospitalization in the 1947 group and for about 20% in the 1957 group.

In 1966 Rappeport and Lassen (10) reported that discharged female psychiatric patients had a higher arrest rate for aggravated assault than did women in the general population.

Revised version of a paper presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

The authors are with New York University School of Medicine, 550 First Ave., New York, N.Y. 10016, and the Bellevue Hospital Center, New York, N.Y. Dr. Zitrin is Professor of Psychiatry, Dr. Hardesty is Research Associate Professor of Psychiatry (Biometrics), Dr. Burdock is Professor of Psychiatry (Biometrics), and Ms. Drossman is Project Assistant. Dr. Hardesty is also Associate Director and Dr. Burdock is also Director, Biometric Laboratory.

This study was supported in part by Alcohol, Drug Abuse, and Mental Health Administration grant MH-15497 from the National Institute of Mental Health.

The authors would like to thank Michael J. Codd, Commissioner, Lt. Daniel McCaffrey, Criminal Records Section, and Lt. Terence F. Bennett, Crime Analysis Branch, New York City Police Department, and Ms. Marjorie L. Smith, M.S.W., Psychiatric Division, Social Work Department, Bellevue Hospital, for their assistance in this study.

In 1967 Giovannoni and Gurel (11) reported on a group of 1,142 psychotic patients whom they followed for four years after discharge from 12 Veterans Administration hospitals. These ex-patients had significantly higher arrest rates for serious crimes (assault, homicide, and robbery) than did the general population. Ninety-five percent of these patients were schizophrenic; a majority had abused alcohol.

The frequency of involvement of schizophrenic patients in serious crimes remains in dispute. In a 1974 report on psychiatric outpatients, Guze and associates (12), who relied on the patients' own accounts of felony convictions, concluded that schizophrenic patients were infrequently involved in serious crimes. In a response to that paper, Paull and Malek (13) offered evidence from a psychiatric court clinic that schizophrenic patients frequently commit both misdemeanors and felonies.

In 1973 Häfner and Böker (14) reported a study done in Germany. They concluded that, although "crimes of violence committed by the mentally ill and the retarded were proportional to the number of such crimes charged to the general population," schizophrenic patients were far more likely than other mentally ill patients to be arrested for violent offenses.

METHOD

In this report we present the results of a study of the arrest records of a sample of patients admitted to the psychiatric division of Bellevue Hospital from Bellevue's own catchment area. At the time the sample was selected (July 1969–June 1971) this area consisted of a strip of Manhattan between 14th and 42nd Streets extending from the East River to the Hudson River, with a population estimated to have been approximately 150,000. Only 20% of Bellevue's psychiatric admissions were from this catchment area; most came from other parts of Manhattan.

During the two-year period July 1969–June 1971 a study sample was assembled from consecutive admissions from Bellevue's catchment area for the purpose of determining the efficacy of a community-oriented mental health program. Although there were some 4,800 admissions from the catchment area in the course of this interval, only about 2,000 of these fell into the sample. Some patients had multiple admissions; the number of admissions ranged from 1–22 per patient over the two-year period. Because of these multiple admissions, the number 4,800 corresponds to only 2,140 individual patients.

Our sample comprised all those consecutively admitted patients who could be screened for catchment area membership, who could be interviewed for a baseline measure of psychopathology by the research staff, and for whom a bed was available on one of the three wards designated for the study. However, because of the high frequency of multiple admissions the 2,000 admissions correspond to only 867 individual patients.

The number of admissions and the number of patients cannot be specified exactly because some patients did not or could not give their names and were listed as unknown; others gave names born of delusions. The identities of some of these patients were never determined because they eloped from the hospital before identification could be established. In addition, many patients gave different names on different occasions; some of these were later identified by ward personnel if they recognized them. However, the study sample of 867 was painstakingly investigated. Therefore, it can be asserted that, with one possible exception, the sample represents a group of individual patients. The exception is a case involving multiple admissions under different names: at one time the admissions were thought to be of 1 person, but later they were considered to represent 2 persons; only 1 person could be found on follow-up, however.

In addition to the sample of 867 patients, we also had data on 977 patients from the catchment area who were screened in the psychiatric admitting office but who did not become inpatients. Some of these individuals came to the admitting office more than once during the study period. As can be seen in table 1, the nonadmitted patients were very similar to the admitted group in sex and age. There were more men than women in both groups of patients, in contrast to the catchment area population, which had more women (see table 1). The age distributions of the two groups of patients are quite similar, with the highest proportion of patients in the 20–50-year-old range. In contrast, the catchment area shows a relatively uniform distribution of ages from 20 to 70.

Among the data subsequently collected were the arrest records for each patient in the inpatient sample (N=867) for the two years before admission to the study and the two years following that admission. The

types of offenses for which patients in the sample had been arrested have been divided into violent offenses and nonviolent offenses. Violent offenses have been further subdivided into those involving direct bodily harm and those involving the potential for harm.

Under the category of violent offenses involving bodily harm were murder, assault, rape, and sexual abuse. Violent offenses with the potential for harm included robbery, burglary, possession of weapons, possession of burglar's tools, arson, and inciting to riot. Nonviolent offenses (exclusive of traffic violations) included, in order of their frequency, public intoxication, possession or sale of drugs or of a hypodermic instrument, disorderly conduct, loitering, resisting arrest, possession of stolen property, harassment, larceny, menacing behavior, and others.

RESULTS

Of the 867 mental patients in our sample, 202 (23.3%) had been arrested at least once during the two years before and the two years after their admission to the study; 117 of these 202 patients (13.5%) had been charged with a nonviolent offense only, and 85 patients (9.8%) had been charged with a violent offense.

Figure 1 shows the age distributions of the patients who had been arrested for at least one violent offense during the study period, those arrested for a nonviolent offense only, and the total sample of 867 patients. The age distribution of the total sample shows a wider dispersion than the age distribution of either of the two groups of patients who had been arrested. This reflects the fact that most arrests of either type were of patients in the 20–40 age range. The age distribution of the group arrested for a violent offense peaks in the 20–30 age interval, whereas more of the patients arrested for a nonviolent offense were in the 30–40 age interval. Moreover, the curve for the group arrested for a violent offense does not extend beyond the 50–60 age interval.

Table 2 shows the distribution of diagnoses among the total admission sample, patients who had been arrested for a violent offense, and those arrested for a nonviolent offense. The patients were classified according to the primary diagnosis recorded at the time of discharge from the hospital. In the sample as a whole, as well as in the group arrested for a violent offense, almost half of the patients were schizophrenic. On the other hand, the proportions of alcoholic and drug-dependent patients who had been arrested for a violent or a nonviolent offense were twice as large as the corresponding proportions in the total sample.

Table 3 shows the diagnoses and arrest records of the 30 patients who had been charged with at least one violent offense involving bodily harm as well as those of the 55 patients who had been charged with at least one violent offense involving the potential for harm. Twenty-one of the patients in each group were schizophrenic. The schizophrenic patients arrested for at least one violent offense involving bodily harm had a mean number of arrests for all offenses greater than that of any of the other diagnostic groups, but the mean number of arrests for all offenses of schizophrenic patients for whom the most serious charge involved potential for harm was lower than that of all but one of the other diagnostic groups.

Table 4 details the offenses charged to the 85 patients who had been arrested for at least one violent offense of either subtype according to the patients' diagnoses. Approximately half of these 85 patients were schizophrenic. Schizophrenic patients were charged with 51% of the violent offenses and 52% of all offenses, compared with 11% and 9%, respectively, for alcoholic patients, 15% and 21% for drug-dependent patients, and 23% and 18% for patients with other diagnoses.

However, only 10% of the schizophrenic patients in the total sample of 867 patients were arrested for violent offenses, compared with 16% of alcoholic

patients, 30% of drug-dependent patients, and 5% of patients with other diagnoses.

Of the 42 schizophrenic patients among the 85 arrested for a violent offense, 20 had a history of alcohol abuse, 8 were at some time drug dependent and alcoholic, and 2 others had also been diagnosed as drug ad-

dicted. Of the 15 patients with a primary diagnosis of drug dependence, 2 had also been diagnosed as schizophrenic and 7 were abusers of alcohol. Of the 10 alcoholic patients in the group arrested for a violent offense, 4 had been diagnosed as schizophrenic on at least one occasion and 1 was drug dependent.

Table 5 shows when the arrest for a violent offense occurred with reference to the time of admission into the study of the 85 patients. There are three groups represented here: those who had been arrested during the two-year period preceding admission into the study but not during the two-year follow-up period, those who had been arrested during the two years following admission but not during the two years preceding admission, and those who had been arrested during both of these periods. Arrests for violent offenses involving bodily harm occurred 1½ times more frequently during the two-year period after admission, but arrests for violent offenses with potential for harm and arrests for nonviolent offenses occurred at about the same frequency before and after admission.

In table 6 the arrest rates per year for major crimes are shown for our sample of 867 patients for the two years before and the two years after their admissions in 1969–1972, for the population of the Bellevue catchment area as a whole in 1972, and for 4,601 cities in the United States with populations over 2,500 in 1972.

In the preparation of this table, the population data for the 4,601 cities were reduced by the proportion of children under age 15 (calculated from table 6 of *Statistical Abstracts of the United States:1971* [15]), and the rates were recalculated from table 27 of *Crime in the United States, 1972* (16, p. 120), with the arrests of children under age 15 omitted. The population figures for the three police precincts comprising the Bellevue catchment area were taken from a study prepared by the Rand Institute and the *New York Times* and reported in the *Times* of July 30, 1973 (17). This population was also reduced by the proportion of children under age 15 in the catchment area, as reported in the tables of the New York City Department of City Planning.

Since each patient's arrest record covers a four-year period, the total number of arrests for each violent offense for the sample was divided by 4 to obtain an annual rate. This method yielded a conservative estimate. Had the arrest rates for the sample been calculated for the single year in which the maximum number of patients was under study, the rates would have been higher. Other factors contributing to the likelihood that the rates given in table 6 are minimal include the following: 1) the death rate in the sample was higher than that in the catchment area, 2) some patients in the sample may not have been in the city during the two years before their admission to the study or may have left the city following discharge from the hospital, so that any arrests they incurred in other cities would not have been counted, 3) periods of hospitalization precluded arrests, 4) a portion of the arrest records for the year 1973 (the terminal year of follow-up) was not available from the New York City Police Department at the time of this writing.

1970–1972 was the period during which the major portion of our sample was under study. 1972 was chosen for the comparison of other urban populations and the Bellevue catchment area population because it was the year with the highest frequency of arrests for crimes of violence in the United States during 1970–1972 (16, p.4). Nevertheless, the frequency of arrests for each of the major crimes listed in table 6 was con-

Burglary	2.31	5.33	8.67

TABLE 7
Proportions of Men and Women Arrested for Major Violent Offenses in the United States in 1972 and in the Bellevue Admission Sample of 1969–1971 (N=867)

Offense Charged	Proportions in United States		Proportions in Admission Sample	
	Percent of Men	Percent of Women	Percent of Men	Percent of Women
Murder	84	16	0	100
Aggravated assault	86	14	91	9
Rape	100	0	100	0
Robbery	93	7	83	17
Burglary	95	5	97	3

siderably higher among our sample and in the Bellevue catchment area than in urban areas of the United States as a whole. Moreover, except for murder[1] and robbery, the rates of arrest for serious crimes for the sample of mental patients were even higher than the rates for their community.

Table 7 shows a comparison of the proportions of men versus women in our sample of 85 patients who were arrested for a major violent offense and shows a similar comparison for the United States as a whole. The data for the United States are from table 35 of *Crime in the United States, 1972* (16, p. 130). The largest difference occurs for the crime of robbery, for which our mental patients showed a higher proportion of women than did the United States as a whole. The proportions for murder in the sample should be interpreted with caution because they are based on a single case.

DISCUSSION

The commonly held belief that the mentally ill commit fewer crimes than the general population is not supported by our study. Indeed, the arrest records of these 867 psychiatric patients from the Bellevue Hospital catchment area show that their rates of arrest for criminal behavior, including violent offenses, are higher than the corresponding rates in their community. Our study was based on admissions to an acute psychiatric service of patients from Bellevue Hospital's catchment area. That the conclusions are not in agreement with earlier reports based on state hospital patients (5–8) may be due in part to differences in methodology. Our results are in general agreement with the reports of Rappeport and Lassen (9) and Giovannoni and Gurel (11).

The presumption that the mentally ill commit fewer crimes than the general population is one factor that has been invoked in support of the current discharge policies of mental hospitals. Because there is a lack of accurate predictive indicators of violent behavior in mental patients, we do not believe that our findings, even if confirmed, will effect any major change in these policies. The prediction of dangerousness, the single most common criterion for involuntary psychiatric hospitalization, is generally conceded to be highly unreliable (18), except perhaps in samples of selected persons at particularly high risk of injury to themselves or others. We are now examining our data on the patients in our study to determine whether we can identify any factors that distinguish patients who were arrested for crimes from those who were not. However, the findings presented here have implications for the postdischarge care of mental patients, particularly if current discharge policies are continued.

The provision of suitable community facilities for treatment, supervision, or follow-up has not kept pace with the needs generated by the discharge of large numbers of mental hospital patients and by more restrictive admission policies. On the other hand, a consequence of the voluntary status of most mental hospital patients today is that they are not required to attend the clinics that are available. It is likely that a system of conditional discharge of some classes of patients with required attendance at outpatient clinics would make possible timely interventions that might prevent criminal behavior or abort full relapses. There is a need to identify those patients for whom such a plan would be useful. To oppose mandatory posthospital care for patients who are known to be at increased risk of dangerous behavior if not supervised is misguided civil libertarianism. Patients who abuse alcohol or other drugs, regardless of the nature of their concomitant or associated mental illness, appear from our data as well as from the work of others (11) to need such care.

The increasing diversion of arrested persons from the criminal justice system to mental hospitals is another factor that might be responsible for the apparent rise in criminal behavior in mental patients. The arrest rate among former hospital patients increases when those who were placed in mental hospitals after an arrest are discharged. Records of convictions of mental patients are less accurate as an index of criminal behavior than records of arrests because many offenders are found in-

[1]Three arrests for murder in our sample have not been counted because they occurred outside of the four-year period of the study.

competent to stand trial or are taken out of the court system before that stage of the legal process takes place. Conviction records would therefore give misleadingly low figures on the criminal activity of the mentally ill.

The treatment of the mentally ill offender has long been a vexing problem. Correctional institutions with psychiatric services have been notoriously ineffective. In New York State all but convicted and sentenced mentally ill offenders are now treated in civil state hospitals. The transfer of mentally ill prisoners from correctional hospitals to civil state hospitals after completion of their sentences, a result of the landmark *Baxstrom* decision (19), has been hailed as a highly successful development in the treatment of this group of patients (20).

However, some recent evaluations of the adjustment of these patients in civil hospitals require a qualification of that judgment. For example, one investigation determined that patients transferred from the correctional hospital at Matteawan were found to have "economically, physically or sexually abused other patients" in the civil hospitals (21). Another study found that some mentally ill offenders in civil hospitals formed a "rapacious subculture" that terrorized other patients and exploited the "staff's tendency to 'treat' people rather than 'punish' them" (22). It seems clear that, although a serious inequity was corrected by removing prisoners who had completed their sentences from correctional institutions, the change in the place of their detention has had multiple consequences, not all of them beneficial.

Although our focus has been on criminal and violent behavior shown by mental patients in the community, these patients are often the victims of crime and exploitation or suffer in other ways from inadequate attention. In pursuit of the laudable goal of removing patients from institutions and placing them in the community, the discharge of the mental patient from the hospital has become for some the standard of successful psychiatric therapy and for others the triumph of individual liberty over social control. However, many of these patients are discharged to fend for themselves—to find lodging in the cheap single-room-occupancy hotels and rooming houses in decaying sections of our cities (23). Few halfway houses are available for discharged patients; moreover, residents of middle-class communities, alleging lack of supervision of the patients, often resist the opening of such facilities in their neighborhoods (24). Instances of kidnapping, imprisonment, and mistreatment of former mental patients by rooming house owners have recently been documented in a New York State court (25).

The special vulnerability of mental patients can be measured in other ways as well. In the follow-up of the 867 patients in our sample we found a death rate more than double the expected rate in the population of the Bellevue catchment area across age categories (24.9 deaths per 1,000 for our patients, compared with 11.2 deaths per 1,000 in the catchment area). The suicide rate was 5.1 per 1,000 for our sample, compared with .08 per 1,000 for New York City as a whole. There were 2 victims of murder among our patients.[2] This would correspond to a rate of 1.15 per 1,000, compared with a rate of .20 per 1,000 for the city as a whole.

COMMENT

This study has not provided answers to the difficult questions of why behaviors that lead to arrest occur among discharged mental patients or how to predict and prevent them. However, the discharge of patients from mental hospitals without provision for decent housing and humane follow-up care for those who require it is regressive. It is not the great social and psychiatric advance that it has been claimed to be.

Change in 1976 Annual Meeting Site

The APA Executive Committee decided to move the May 10-14, 1976 APA Annual Meeting from Atlantic City to Miami, Florida, after hearing the APA Meetings Management Department report that it had ascertained that a major Atlantic City hotel had inadvertently committed several hundred rooms to another organization during the week the APA meeting was scheduled. This would have left APA with the unacceptable alternative of using a myriad of scattered small hotels in the Atlantic City area. It has been confirmed that Miami Beach can accommodate the meeting.

Further arrangements and developments will be reported in future issues of *Psychiatric News*.

Cluster Analysis Profiles of Suicide Attempters

BY ARI KIEV, M.D.

The author reports the results of a three-stage cluster analysis of data on 298 patients who attempted suicide. Patients were allocated by the analysis to seven identifiable profile types that correlated with six outcome variables. These profiles include data on the social setting and the seriousness of the attempt and judgments about overall functioning and interpersonal conflict as well as the input of the patients' significant others. The author states that these profiles have prognostic significance as well as implications for the treatment of suicide attempters and the education of emotionally involved significant others.

THE DIFFICULTIES INHERENT in developing valid criteria for estimating the prognosis of suicidal crises stem from the fact that the psychological and social factors leading to the suicide attempt have often passed or subsided by the time evaluation occurs. The psychiatrist must deal with probabilities on the basis of factors that cannot be observed but can only be inferred by the patient's history and the accounts of emotionally involved significant others.

Factor analysis of the 56-item Life Crisis Inventory, which was developed for a one-year follow-up study of 300 patients who attempted suicide (1), pointed to the prognostic importance of three factors: interpersonal conflict, the social setting of the attempt, and the attitudes of significant others.

This paper examines the results of a hierarchical clustering technique designed to condense nine Life Crisis Inventory factor scores and four variables regarding significant others for each patient in a sample of 298 suicide attempters (the number of the original cohort of 300 for whom sufficient data were available) into clinically relevant profile or prognostic types.

METHOD

The analysis involved three stages: pattern extraction, or R analysis (2), to compress the patient-variable dimensions; Ward's hierarchical grouping technique (3, 4) to define the symptom types of attempters; and a "scrubbing" procedure (5) to test the fitness of each person to this cluster, to reassign misfits and overlaps, and to eliminate isolates.

RESULTS

Of the total sample examined (N=298), 245 patients (82%) could be allocated to seven clearly identifiable types. Misfits were reassigned to the cluster they most suitably fit, and isolates and overlaps were identified and omitted from the remaining analysis. Outcome profiles for each of these cluster types on six outcome variables were then established by means of a discriminant analysis. The resulting function discriminating the cluster types shares 41.3% of its variance with the six outcome variables. (The computer program used to calculate the function, DISCRIM, also prints the canonical correlation [.541, p=.006].)

The following descriptions characterized the seven profile types.

Type I: Suicidal Gesture

Type I, the largest clustering, consisted of patients with characterological problems who experienced few symptoms of anxiety, guilt, or depression; minimal dysfunctioning and minimal interpersonal conflict; and alcohol and/or drug abuse. Denying the presence of psychiatric difficulties or attributing their problems to situational factors, patients who fit this profile type made the least severe attempts of all seven groups. They reported no plans for the attempt, minimal suicidal intent, no real desire to die, minimal suicidal thoughts, and minimal discomfort before the suicide attempt. They attempted suicide with pills or by slashing their wrists in the presence of others or with others nearby, although no significant others were available for interview at the time of admission. Despite repeated low-risk attempts, these patients tended to have good general outcomes; they showed little increase in conflict or in symptoms at one- and two-year follow-up.

Type II: Acute Depressive Reaction

Type II, the second largest clustering, consisted of acutely depressed patients who believed themselves to be incapable of coping with objective life stresses and attempted suicide with irreversible means in a setting

Revised version of a paper presented at the 127th annual meeting of the American Psychiatric Association, Detroit, Mich., May 6–10, 1974.

that held minimal possibilities of rescue.

These patients reported the highest scores on the somatic symptoms of depression, including appetite, sleep, and sex disturbances, as well as high scores on anxiety, tension, fear, and remorse. They reported minimal interpersonal conflict with significant others, who tended to be supportive.

The social setting of the suicide attempts of this group of patients—at a distance from others and with minimal possibility of rescue—despite the supportive attitudes of significant others, earmarked this high-risk group. In the year following the attempt, these patients showed the highest scores on increased conflict, the second highest scores on subsequent hospitalization, relatively high scores on increased symptoms, and some subsequent attempts.

Hospitalization should be seriously considered for this group of patients. They require prompt reduction of depressive symptoms with ECT or psychopharmaceuticals. Special precautions should be taken when a patient who fits this type appears to improve but has not yet come out of his depression.

Type III: Passive-Aggressive and Passive-Dependent Personality Disorder

Type III patients reported a minimum of symptoms and interpersonal conflict. Judged by significant others to be quite dysfunctional, these patients had been hospitalized in the past more often than any of the other groups. They attempted suicide in a remote and private way, using irreversible means and making no effort to obtain help. In the year following the attempt, they made the fewest major changes in their lives and were judged generally to have the worst clinical outcomes, despite the absence of repeated attempts. They scored none or minimal on ratings of suicidal preoccupation and obsessive thoughts or acts. They showed little evidence of emotional or physical blunting of affect and received the lowest scores on unusual thoughts and behavior of any of the groups. They also had mild and minimal ratings on gradiosity, hallucinatory behavior, and bizarre thought content. They were rated as minimal to mild on anxiety, guilt, tension, and depressive symptoms.

A history of a serious suicide attempt in an isolated social setting without the seeking of help and a discrepancy between these patients' views of their problems (they minimized them) and the views of significant others (who may have been indifferent, rejecting, punitive, or overcontrolling in their concern for the patients' welfare) made this a high-risk group.

Treatment goals for patients who fit this type must be designed to reduce their high rate of dropping out of treatment. Brief hospitalization should be considered to reduce the pressures brought by significant others and to arrange less noxious living arrangements for these patients. Long-range supportive programs may prove to be the most satisfactory way of keeping contact with them. At the same time, significant others should be helped to reduce their excessive guilt and sense of responsibility.

Type IV: Anxiety Reaction with Interpersonal Conflict

Of the seven groups, type IV patients were judged to have the highest scores on anxiety and guilt and the second highest scores on tension, suicidal threats, and interpersonal conflict, despite reports of significant others that they were supportive of the patients and nonthreatened. While patients who fit type IV attempted suicide in close proximity to others with reversible methods—e.g., lacerations and pills—they were judged to be above average in suicide potential.

Type IV patients received average scores for unusual thoughts and emotional and physical blunting and the lowest scores on depressive symptoms and overall dysfunctioning. They seemed to be making good adjustments.

The most prominent feature of this group appeared to be the marked discrepancy between the patients' high scores for interpersonal conflict and the significant others' accounts of being supportive, which no doubt contributed to the persistence of high levels of interpersonal conflict, the highest incidence of repeated attempts, and the second highest scores on symptoms in the year following the attempt. These patients reported considerable interpersonal conflict with significant others, who viewed themselves as supportive and minimized the patient's distress. The discrepancy between the patient's subjective sense of rejection and the reports of the significant others' indifference led to repeated attempts, a persistence of symptoms, and continued interpersonal conflict.

Treatment for this group of suicide attempters must ultimately focus on the resolution of interpersonal conflict and reduction of related anxiety and tension. Outpatient treatment and family therapy may be most relevant because hospitalization is unlikely to resolve the problem.

Type V: Socially Isolated

Type V patients, who were characterized by very high scores on interpersonal conflict, suicide potential, and unusual thoughts and behavior, attempted suicide at a distance from others and made no effort to be rescued. Despite this, significant others judged their functioning to be unremarkable, a finding with substantial prognostic implications. Of interest and possibly related to their social isolation, type V patients (like type VII patients, described below) could not be personally evaluated at the time of the one-year follow-up.

The inclination of this group of patients to drop out of treatment should be recognized. Efforts should be made to establish a long-range supportive and contact program for these patients, with simultaneous efforts directed toward the education of significant others, who must be helped to understand the seriousness of the problems of these patients.

Type VI: Suicidal Preoccupation

Type VI patients constituted a group who were diagnostically similar to type I patients except for high scores on unusual thoughts and behavior and the highest score of any group on suicide potential. These patients reported more obsessive thoughts and interpersonal conflict than type I patients, although their scores were close to the mean. They experienced little anxiety, guilt, or depressive symptoms and only minimal dysfunctioning. They were close to the mean on emotional withdrawal and physical blunting, and they attempted suicide in close proximity to others.

At one year, type VI patients had made the most major changes. They had high scores on increased symptoms but had made no subsequent suicide attempts.

In essence, type VI patients presented more serious characterological problems than type I patients as well as the highest scores on the factor measuring suicide potential. They made relatively nonserious attempts in close proximity to others in the face of situational problems but appeared to have good one-year outcomes, probably related to the major changes they were able to make in their lives.

Type VII: Chronic Dysfunctional

Type VII patients resembled type III patients in that they had low scores on anxiety and guilt and attempted suicide at a distance from help, using irreversible means. They also had high scores on interpersonal conflict, suicide potential, and significant others' ratings of overall dysfunctioning and rejection.

They differed from type III patients in that they had higher scores on obsessive thoughts, suicidal preoccupation, and overall dysfunctioning, the highest scores on emotional and physical blunting, and some evidence of depressive symptoms.

DISCUSSION

Threatened or attempted suicide cannot be lightly dismissed as attention-seeking behavior. People who attempt suicide often come close to death. Those who threaten suicide or who make less serious attempts may kill themselves in subsequent attempts.

To the extent that suicide does not occur unpredictably it can be prevented if proper attention is paid to long-range prognosis and degree of risk.

The results described here of a cluster analysis underscore the importance of evaluating the effects of discrete variables that may act simultaneously and perhaps synergistically to increase suicidal risk. Particular emphasis must be given to the views of significant others regarding the patient's symptoms and need for treatment, the presence of interpersonal conflict, and the discrepancy between the attitudes of the patient and of significant others.

The groups at highest risk of suicide appear to be patients suffering from psychoneurotic illnesses with depressive or anxiety symptoms who are involved in interpersonal conflict and patients with longstanding characterological problems associated with nonfunctioning and considerable interpersonal conflict. Socially isolated patients, who tend to disappear from follow-up, represent an additional high-risk group.

The attitudes of significant others toward the patient, his illness, and his suicide attempt have major significance in assessing prognosis. Patients with the highest scores on depressive symptoms and serious suicide attempts reported considerable conflict with significant others at the end of one year after their suicide attempt, suggesting that increased interpersonal conflict subsequent to an attempt may be reflected in rehospitalization, increased symptoms, and subsequent attempts.

In contrast to depressed patients, those with substantial anxiety reactions reported considerable interpersonal conflict, which contrasted markedly with the accounts of significant others, who considered themselves to be supportive and nonthreatened by the attempt. The discrepancy between the views of patients and those of significant others may have been reflected in the high incidence of repeated attempts and the increase in symptoms in this group of patients.

The significant others in the passive-dependent, passive-aggressive group conveyed indifferent and rejecting attitudes, which were at considerable variance with the average scores on interpersonal conflict reported by the patients, whose isolated attempts were above average in intention and lethality.

The significant others of the socially isolated patients also reported indifferent and rejecting attitudes, but this corresponded to the perceptions of the patients, who had the highest scores on interpersonal conflict and who attempted suicide in isolation.

Psychiatric illness may too often be mistakenly rationalized as attributable to factors other than mental disease. Failure to recognize the patient's need for treatment may lead to an escalation of conflict and stigmatization of the patient unless appropriate efforts are made to educate both patients and their significant others as to the nature of the problem.

As has been shown in previous reports (1, 6, 7), the attitudes of significant others appear to relate to the outcome of suicidal patients—whether in terms of their ignoring the presence of a treatable illness or in terms of their creating a nonsupportive, punitive, or noxious environment for the patient. These factors have relevance for assessing the immediate risk following a suicide attempt and for the continuing management of the patient. If symptoms improve but negative attitudes persist, prognosis must necessarily be guarded.

COMMENT

The clinical descriptions of the seven profile types given here illustrate the relevance of considering the

simultaneous interaction of these variables in determining prognosis for suicide attempters. These profiles held up over the period of follow-up. They demonstrate an empirical consistency and validity that gives them prognostic significance. The high correlation between initial and outcome variables further supports the validity of these profiles, which have been theoretically and factor-analytically determined.

APA Grant Program for Minority-Group Medical Students and Residents

A small number of qualified minority applicants (including but not limited to American Indians, Asian Americans, black Americans, and Spanish-speaking Americans) will receive residency stipends, assistance in selecting a residency program, expenses to a yearly meeting with other minority fellows to share experiences and administrative help through APA's Office of Minority Affairs. The program is sponsored by APA, with funds provided by the National Institute of Mental Health.

Applications are being accepted now for residencies beginning in July 1976 and subsequent years. Applicants must be U.S. citizens and must have graduated from a U.S. medical school or possess the ECFMG certificate.

For further information write Jeanne Spurlock, M.D., Office of Minority Affairs, American Psychiatric Association, 1700 18th Street, N.W., Washington, D.C. 20009, or call (202) 232-7878.

The Behavior Therapies: Therapeutic Breakthrough or Latest Fad?

BY ARTHUR K. SHAPIRO, M.D.

The author critically examines the evidence for the effectiveness of the behavior therapies as described in the American Psychiatric Association's task force report on behavior therapy. He concludes that current attempts to evaluate behavior therapy suffer from inadequate methodology and that the claims for its therapeutic efficacy are excessive and unsupported by the controlled clinical evidence.

THE BEHAVIOR THERAPIES, increasingly used in the treatment of emotional disorders, have influenced treatment by psychiatrists and are one of the major therapies used by psychologists. If the trend continues, behavior therapy[1] may become the predominant therapeutic modality taught to and practiced by psychologists, replacing insight-oriented, client-centered, rational, and other types of psychotherapy. This trend is evident in the many training programs that have been established throughout the country (1) and in the exponential increase in the publication activity in the field of behavior therapy, which now yields more publications than any other therapy (2). Further serious consideration of behavior therapy was stimulated by the favorable report of the American Psychiatric Association's Task Force on Behavior Therapy (3).

This new development in psychotherapeutics raises important scientific and pragmatic issues and questions. If the theory is correct, and if it can be substantiated by appropriate clinical evidence, two important alternatives must be considered. Either psychiatrists will have to spend considerable time and energy in mastering the theory and practice of behavior therapy, or this therapy will increasingly be conducted by psychologists.

The question of whether behavior therapy is a therapeutic breakthrough or a recent fad is therefore an important scientific and pragmatic one. Because the APA task force report is an important summary document that has had and will continue to have an important influence on psychiatry, this paper will focus on and be limited to the advantages of behavior therapy as described in nine points in this report. The nine points will be discussed serially as they appear in the report.

Modified version of a paper presented at the 219th scientific meeting of the New York County District Branch, New York, N.Y., October 10, 1974.

Dr. Shapiro is Professor of Clinical Psychiatry and Director, Special Studies Laboratory, Payne Whitney Clinic—Cornell University Medical College, 1300 York Ave., New York, N.Y. 10021.

[1]The term "behavior therapy" is used in this paper in the broad sense of the heterogeneous group of behavior therapies.

ADVANTAGES OF BEHAVIOR THERAPY

Behavior therapy developed largely from experimental psychology in the laboratory and is distinguished from alternative clinical approaches because it is based on experimental behavioral science. Behavior therapists claim superiority for their technique because their therapy is based on theory derived from the laboratory.

But let us not forget the harmful effects of overelaborate theoretical formulations in medical history (4). Medical history is in part the succession of overdeveloped theory and practice, corrected by a simple empiricism that, in turn, becomes overelaborated (5). In the past erroneous theory imposed on treatment often led to clerics, empirics, apothecaries, and charlatans being more correct than physicians (6). Although theory derived from experiments in the laboratory may be an important lead for clinical practice, it may be clinically irrelevant. For example, placebo effects occur less frequently in laboratory experiments than in clinical situations (7). In addition, quantifiable and reliable laboratory tests of suggestibility do not correlate with placebo effects in clinical situations or with subsequent clinical course, whereas placebo effects do tend to correlate with clinical course (8–10). An established principle in pharmacology is that the data derived from the laboratory (e.g., in vitro, specific species, or animal studies) cannot be safely generalized to man. The hypotheses derived from such data have to be repeated in man.

Reppucci and Saunders (11) came to a similar conclusion. They stated, "Although claims of the success of applied behavior modification as a vehicle of institutional and individual change are widespread, convincing empirical evidence is limited to laboratory and highly financed, small demonstration projects. Thus, the usefulness of current behavior modification techniques in natural settings is unclear." (p. 658)

Behavior therapy methodology requires and leads to the clinical behavior therapist objectively analyzing,

describing, and quantifying the clinical problem, treatment, and evaluation.

This claim is made repeatedly by behavior therapists. However, all clinicians make this claim, and behavior therapists are merely repeating it, using research instead of clinical jargon (12–14).

Most of the reported case histories and behavioral analyses are very complicated, primarily unverified suppositions, and merely stated to be objective by the behavioral analyst. Supporting data such as studies of reliability, validity, and the psychometric properties of the concepts and their measurement are generally absent from the behavior therapy literature, and when present are limited to behavioral observations and target symptoms. I suspect that the reliability and validity would be as low for behavioral analyses as they are for psychiatric diagnosis and psychodynamic formulations.

Behavior therapy is applicable to both psychological and organic illnesses.

This concept is untrue, adherence to it may be harmful and occasionally lethal, and it is often pragmatically irrelevant. At a minimum it should be used only after careful consideration of other alternatives. Many organic illnesses are influenced by stress and psychological factors, but no one today would treat syphilis except with penicillin, pellagra except with nicotinic acid, diabetes with anything but insulin, and so on. However, behaviorists mistreat and harm patients with Gilles de la Tourette's syndrome when they use behavior therapy instead of haloperidol (15, 16) and when they interpret the symptoms as voluntary, manipulative expressions of anger (17–20). It is questionable whether teaching children to behave or improved management of mentally retarded children should be classified as a psychiatric, medical, or psychotherapeutic treatment.

Patients with chronic disabling problems who have failed to respond to other forms of psychotherapy have shown well-documented and substantial improvement with behavioral procedures.

It is curious that this claim is made by all psychotherapeutic schools, as well as by charlatans whose patients have failed to respond to other therapies. It should not be forgotten that despite the tendency to glamorize and sentimentalize medical history, until recently medical treatment could be characterized as the history of the placebo effect, since almost all medications were effective primarily because of the placebo effect (5). Placebo effects have been appreciated throughout medical history but are most easily appreciated only when attributed to others. It is impressive that one's sensitivity to the placebo effects of others is no guarantee against developing beliefs in one's own placebo effect. There are many historical illustrations, few or no exceptions (5, 6), and at least 3 studies that demonstrate this kind of defensiveness (12–14, 21).

Evaluation of outcome is more common in behavior therapy than in other kinds of psychotherapy.

This claim is without substance, since most clinicians claim that they continually evaluate outcome, reformulate hypotheses, and reevaluate outcome. More important are the specific procedures that are used and the type of evidence collected to assess outcome.

The APA task force report goes on to describe three types of research designs that have been used to assess the effectiveness of behavior therapy.

The individual subject, or own control design has shown the efficacy of behavior therapy in treating a variety of disorders.

This efficacy was illustrated by several studies of changes in the ward milieu and social behavior of psychotic patients (22, 23), and claims were made for similar effectiveness in neurotic and mentally retarded patients.

The multiple-baseline design is considered an important and frequently used method.

In this study design, several patient problem behaviors are measured and the therapeutic intervention is used for only one of the behaviors. If that behavior changes, it is argued that the treatment intervention is specific. If all of the behaviors change, it means that the effect is nonspecific, i.e., it is a control for the placebo effect of treatment.

Let us consider the two previous designs together by briefly discussing the data in the literature on the placebo effect (8). All clinical studies using placebos as controls report positive, neutral, and negative placebo effects. Placebo effects occur more frequently in clinical situations than in laboratory experiments. These two well-established observations suggest that placebo effects would be highly likely concomitants of behavior therapy. The own-control and multiple-baseline designs lead to the *post hoc, ergo propter hoc* fallacy. It is an elemental and generally accepted principle but usually applied to someone else's theory or therapy and frequently overlooked about one's own (12, 14). It is common in medicine among clinicians and especially psychotherapists and psychoanalysts. Many behavior therapists, including many experienced researchers, commit this error.

Behaviorists point out that therapeutic change during psychoanalysis cannot safely be attributed to insight into the unconscious. Without additional evidence, it must also hold that therapeutic change cannot be attributed to conditioning procedures.

My impression, from reading many case reports and from clinical contact and consultation with behavior therapists, is that much more than the application of conditioning principles goes on in the treatment of patients by behavior therapists. In fact, the actual conditioning seems to account for only a very small part of the treatment compared to various other potential "placebogenic" factors, such as support, education, persuasion, exhortation, drugs, and many other non-

specific factors used to one extent or another in all therapies. The recent trends toward treating the whole patient or family and broad spectrum behavior therapy are testimony to the use of many modalities. In fact, as I read and hear reports of the treatment of patients, I am impressed that behavioral procedures are very similar to my own, except that the descriptive jargon differs from my jargon.

I was disappointed by the claim of behavior therapists that their therapy is superior to other therapies, a claim that is based on their self-assessed clinical reports compared with the self-assessed clinical reports of others. Behavior therapists rigorously criticize clinical studies reporting success in psychotherapy, but the same rigor is not applied to studies of successful behavior therapy.

But all of these speculations are unimportant compared to the definitive basis for evaluating the effectiveness of a treatment, that is, the data from carefully controlled studies, as described in the following section.

The experimental group/control group design can provide useful information on the efficacy and cost-effectiveness of behavior therapy.

This design, used extensively and successfully in drug studies (24–26), would compare behavior therapy with a control that may be an inert procedure, an active but nonspecific procedure, or another traditional or standard therapy. Although establishment of efficacy requires this kind of evidence, the task force report describes only 2 frequently cited studies of this type (27, 28). Paul's study (27) of desensitization therapy was seriously flawed because the subjects were nonclinical volunteers with anxiety in public speaking situations, and his findings could not be replicated in a clinical study of the treatment of children with phobias (29). The other research cited was Gelder and Marks' study (28) of classic phobias in outpatients who were treated weekly for about a year with desensitization, group, or individual therapy. Desensitization therapy led to the most rapid and best improvement. These 2 studies are inadequate evidence for, and do not warrant, the sweeping conclusions of the task force report about the efficacy of behavior therapy.

As part of a comprehensive review of the evidence for the effectiveness of psychotherapy, Luborsky (30) compared behavior therapy with psychotherapy. In his review he included only studies with genuine patients and excluded those with student volunteers, subjects with habit disorders such as bed-wetting, individuals with addictions such as alcoholism, and subjects with other bad habits. Nineteen controlled comparisons in 12 studies between behavior therapy (primarily desensitization) and individual therapy met minimum standards for inclusion in the review. Thirteen of the comparisons showed no difference in efficacy, 6 favored behavior therapy, and none favored individual psychotherapy. Five of the 6 comparisons favoring behavior therapy were of poor research quality and received the lowest ratings for adequacy of methodology. In addition, the therapies were brief, most of the studies were conducted by behavior therapists, and there was a tendency for benefits to appear early with behavior therapy and later for psychotherapy. This last finding may be related to the fact that behavior therapy is more structured and time-limited than psychotherapy. Luborsky could not draw any conclusions from these data.

In an important recent study (31) 94 psychiatric outpatients with anxiety neurosis or personality disorder were treated for 4 months by senior behavioral or psychoanalytically oriented therapists or assigned to a waiting list control. At 1- and 2-year follow-up assessment with multiple, comprehensive measures, all groups were equally and significantly improved.

In another study (32), hyperactive children were treated for 8 weeks with methylphenidate alone, behavior therapy and methylphenidate, or behavior therapy and placebo; they were evaluated with multiple measures during therapy and 4 weeks after therapy. In a preliminary report for 36 subjects, significant improvement occurred with all of the treatments but was significantly greater and less costly using methylphenidate alone.

Some studies have questioned the results of aversive conditioning in alcoholism (33), implosive therapy and flooding procedures (34), the clinical significance of self-control of cardiac functioning (35), and the evidence supporting the presumed specific or essential procedures used in systematic desensitization (36).

Wolfe (37), in a study of the major findings from 20 review articles in the literature, concluded that

> 1) The research on the behavior therapies is surprisingly lacking in rigor. Pawlicki (1970) estimates that only 4 percent of the studies met Eysenck's three criteria of control group, baseline measurements, and follow-up assessments.
>
> 2) There appears to be an increasing awareness on the part of behavior therapy practitioners of the complexity of clinical disorders. This is evidenced by the fact that most of the reviews discussed ways of making a particular therapy more effective by combining several techniques, by focusing more on imagery techniques, and by emphasizing the patients' responsibility in developing their own behavior program.
>
> 3) While one or another behavior therapy has achieved some positive results for some patients with specific problems, generally these therapies produce part-successes, alleviating only some aspects of the patient's problems. Furthermore, a problem which afflicts all of the behavior therapies is their typical failure to produce results which generalize beyond the treatment setting.[2]

Another theme in the history of medicine is apparent: first the optimists, then the skeptics, and finally, one hopes, a reality synthesis.

[2]Reprinted by permission from "The Success of the Behavior Therapies: A Report on 20 Reviews," by Barry E. Wolfe (unpublished manuscript), 1974. Copyright 1974, Barry E. Wolfe.

Behavior therapy is highly effective, ameliorative, or promising in the treatment of many disorders.

The task force report concludes that behavior therapy can be used in the treatment of phobias, anxiety, enuresis, stuttering, obsessive-compulsive behavior, hysteria, encopresis, psychological impotence, transvestism, exhibitionism, gambling, obesity, anorexia, insomnia, nightmares, temper tantrums, head bumping, thumb-sucking, excessive scratching, and excessive verbal demands. The report concludes that it is also useful in treating rebellious behavior, sibling rivalry, isolate behavior, elective mutism, hyperactivity, difficulties in social interaction, classroom disruption, failure to study, low academic performance, social behavior in chronically ill mental patients, verbal and nonverbal behavior of psychotic and schizophrenic children, and the tics associated with Gilles de la Tourette's syndrome.

My response to these claims is to refer to Garrison (38), America's major medical historian, who was able to discern some lawfulness in the historic sea of medicine's ineffective remedies. He observed that "Whenever many different remedies are proposed for a disease, it usually means that we know very little about the disease, which is also true of a . . . [remedy] when it is vaunted as a panacea or cure-all for many diseases" (p. 25).

Contemporary psychotherapy, including behavior therapy, is consistent with this history. Many psychotherapists claim superior results in the treatment of psychological illness, and each tends to claim cures for many illnesses (12–14, 39).

The statements in the APA task force report about the effectiveness of behavior therapy in Gilles de la Tourette's syndrome may illustrate the tendency to uncritically exaggerate outcome data. The effectiveness of behavior therapy in treating this syndrome is referred to three times in the report, with four supporting references:

> behavior therapy techniques have . . . been shown to be effective in reducing the characteristic multiple tics [in Gilles de la Tourette's syndrome] (19, 40). (p. 29)
>
> Behavior therapy has been highly effective with . . . tics associated with Gilles de la Tourette's syndrome (19, 40). (p. 36)
>
> [Negative practice] . . . has been successfully used with some patients in whom the tic was part of a Gilles de la Tourette's syndrome (20, 41). (p. 22)

My subsequent comments are based on my experience with and study of over 250 patients and treatment of about 150 patients with Gilles de la Tourette's syndrome (16, 42, 43).

All of the case reports referred to in these references (19, 20, 40, 41) were carefully reviewed. A detailed review will be published elsewhere (43). Of the 17 patients, 1 had blepharospasm (41), 2 did not fulfill the criteria for a diagnosis of Gilles de la Tourette's syndrome (20), and for 6 the information was inadequate to make the diagnosis (20, 44). Of the 6 with inadequate information, 4 had remissions that were incomplete or not generalized, 2 were treated with concomitant chlorpromazine or amobarbital. Of the remaining 8 patients with adequate information for the diagnosis of Gilles de la Tourette's syndrome, 1 withdrew from treatment (20), 1 failed to improve (20), and 3 were reported to have improved at 4-year follow-up; unfortunately, two of these reports were based on self-reports from the patients (20). The results for the remaining 3 patients were unconvincing and not supported by the data; 1 patient was treated with concurrent haloperidol (40), another with thioridazine (19), and the third patient with extensive psychotherapy and residential treatment for 2 years (19).

Thus of 8 patients with adequate information for the diagnosis of Gilles de la Tourette's syndrome, 2, or 25%, may have improved. This amount of improvement is exactly the same as that obtained by our research group for patients who were evaluated 7 months to 8½ years after their initial evaluation (16). The average improvement for patients not receiving haloperidol was 25%, which contrasts with a 75% average improvement for patients receiving haloperidol. These trends were confirmed by two studies (45, 46) of single patients treated with massed or negative practice and aversive stimulation. Symptoms in both patients were decreased only during the period of treatment and were markedly and consistently reduced in 1 patient (45) after treatment with haloperidol.

Our research group has studied over 250 patients with Gilles de la Tourette's syndrome. About 38 were previously treated with various behavioral procedures in other centers, and 2 patients were similarly treated, unsuccessfully, in our laboratory. Many patients reported that their symptoms decreased while they concentrated on the procedure (all such patients report that their symptoms decrease when they are absorbed in nonanxious tasks), but none reported any permanent, lasting, or generalizing effect outside of the treatment situation. Although we may be seeing a biased sample of failure (the successes may not get to us), I think it unlikely that behavior therapy has any substantial beneficial therapeutic effect on the symptoms of Gilles de la Tourette's syndrome. Considering the extensive negative clinical experience, the inadequate evidence from the literature about the effectiveness of behavioral techniques, and especially the successful use of haloperidol (15, 16), I would consider the recommendation for and use of behavior therapy in treating this syndrome as indefensible at the present time, except perhaps as an experimental procedure requiring informed consent by the patient.

Yates (20), who is frequently referred to and extensively quoted in the APA report and who has studied and treated tics quite extensively, is more thorough, cautious, and tentative about his conclusions than the members of the APA task force. He has stated,

> Virtually all of the studies reviewed are seriously defective in the adequacy of follow-up data. (p. 201)

> Thus the results reported by behavior therapists must be treated with extreme caution and should be regarded for the present as experimental studies of the control and manipulation of these forms of maladaptive behavior, rather than as therapeutic in intent or result. (p. 202)
> One of the major problems of the behavior therapist relates to the transfer of results obtained in a laboratory to real-life situation. . . . Results produced in an impersonal laboratory situation are not very likely to transfer very strongly outside the laboratory. Hence, the strictly laboratory-based studies must be regarded as a preliminary to the attempt to abolish the behavior outside. (p. 203)
> [such studies have] . . . only begun to be applied to the control and modification of tics. (p. 204)

I wonder how many of the other enthusiastic claims in the task force report would weather a critical, in-depth analysis of outcome.

CONCLUSIONS

My impression is that the APA task force report is a well-written, concise summary about behavior therapy that successfully serves to inform psychiatrists unacquainted with the principles of behavior therapy. However, I do not believe that the evidence supports the extensive claims made about the clinical effectiveness of behavior therapy. The arguments, in general, are similar to the claims of all clinicians, past and present, except that they are couched in experimental research parlance.

Despite these limitations, enough clinical evidence has been amassed to seriously consider behavior therapy as a therapeutic breakthrough. However, it is a promise as yet unfulfilled. A major potential asset of behavior therapy is the tendency by psychologists (especially experimental psychologists), who use it most, to study and evaluate their procedures and results. Unfortunately, the studies have not been very successful and suffer from inadequate methodology. The therapeutic claims for behavior therapy are excessive and have outdistanced the controlled clinical evidence. Behavioral procedures are being used in an undisciplined way, too extensively, and by inadequately trained clinicians. In this sense behavior therapy may be the latest fad.

Sufficient data have been obtained to suggest that clinicians should become further acquainted with behavior therapy. I would consider using it and would refer patients to skilled therapists for treatment of selected clinical problems. I would also recommend that psychiatric residents interested in learning about and using behavior therapy have available to them a skilled behavior therapist for teaching and supervision. However, I would consider it premature to replace other more traditional (especially data-oriented) therapeutic techniques with behavior therapy until evidence of its effectiveness, in the form of controlled comparative studies, becomes available. I am somewhat concerned and would recommend to behavior therapists that standards of education and clinical experience be established to prevent unqualified and potentially dangerous treatment for unwary patients. It should be appreciated that these remarks, although directed to behavior therapy because it is the subject being discussed, apply equally to all schools of psychotherapy (8).

The question of whether behavior therapy is a therapeutic breakthrough or the latest fad can best be answered in the future only after adequate evidence in the form of well-controlled studies has accumulated. Unfortunately, current attempts to evaluate the behavioral therapies have not been very successful and suffer from inadequate methodology. At the present time, therefore, the balance is more in the direction of the behavioral therapies being the latest fad rather than a therapeutic breakthrough.

Psychiatric Aspects of Dwarfism

BY JAMES S. BRUST, M.D., CHARLES V. FORD, M.D., AND DAVID L. RIMOIN, M.D., PH.D.

Sixteen adult dwarfs–11 with achondroplasia and 5 with hypopituitarism–were studied by means of psychiatric interviews and psychological tests. There were no significant differences between the two groups; in general, the subjects had achieved a satisfactory life adjustment despite the stress of having bodies uniquely different from those of the general population. They had secure identities as "little people" and successfully used coping mechanisms such as a sense of humor and a pleasant interpersonal style. Male dwarfs tended to experience more emotional distress than female dwarfs.

ALTHOUGH INTENSIVE medical research has provided much information regarding the diagnostic classification, etiology, and, more recently, treatment of dwarfism (1–3), there has been relatively little investigation into the psychological and emotional aspects of these disorders. This report represents a review of the literature and a clinical study of the psychological status of two groups of adult dwarfs. One group consisted of subjects with achondroplasia, a disorder that results in disproportionate short stature: the arms and legs are small in proportion to the trunk. This disorder is inherited as an autosomal dominant trait, but the majority of the cases are sporadic and presumably represent new mutations. The second group consisted of subjects with hypopituitary dwarfism, a disorder that results in proportionate short stature and may be associated with other pituitary hormonal deficiencies, particularly of the gonadotropins.

The authors are with the School of Medicine, University of California, Los Angeles, where Dr. Brust is Assistant Clinical Professor of Psychiatry, Dr. Ford is Adjunct Associate Professor of Psychiatry, and Dr. Rimoin is Professor of Pediatrics and Medicine. REVIEW OF THE LITERATURE

Of those psychological elements which have been studied in dwarfs, intelligence has received the most interest. Most authors have reported that dwarfs have normal intelligence with a normal distribution (4–10); however, Spencer and Raft (11) found an average IQ of 83 in two subjects with hypopituitary dwarfism. There has also been some evidence of a verbal-performance disparity in subjects with pituitary (12) and achondroplastic (4) dwarfism. Studies concerning level of school performance have reported conflicting findings (9, 10).

Many authors see a potential for the development of emotional difficulties in individuals of dwarfed stature. This follows from the observations that merely the small size attracts unusual attention and that there is a tendency for the dwarf to be treated as if he were younger (4, 5, 7, 9, 12–18). Adolescence has been regarded as an especially difficult period (14). Personality traits are not stereotyped, but the frequent occurrence of some traits has been noted. These include immaturity and dependency (7, 14), extroversion (12), latent depression (7, 12, 15), and the absence of overt aggressive behavior (15). Ego-defense mechanisms include denial (14, 16, 17), exaggeration (7, 14), obsessive-compulsive defenses (15), and withdrawal or social isolation (4, 17, 19). Other efforts that dwarfs use to achieve mastery over their specific situation include adopting the role of mascot (14, 17), the use of humor (14), and the use of scholastic achievement (10). Special note has been made by Money and associates (4, 17) of "chronic cheerfulness" and "optimism" in children with achondroplasia.

Money and Pollitt (16) have investigated the psychological response of hypopituitary dwarfs to treatment with human growth hormone. It was their feeling that the degree of psychological maturation in the dwarfed child under treatment related not so much to the amount of growth, but rather to the ability of the parents and other adults to treat the child according to his age instead of his size. They have also described a "readjustment syndrome" reflecting a range of difficulties in accepting the treatment. Symptoms varied from feelings of pressure to perform better to outright refusal of the treatment. This seems to be due to an identity crisis brought about by the prospect of change from a familiar, albeit abnormal, situation. Another

response to such treatment has been decreased denial and immature behavior coupled with increased overt depression and anger (7).

METHOD

The Medical Genetics Clinic at Harbor General Hospital treats a large number of dwarfed patients. From the census of this clinic, patients with a definite diagnosis of either hypopituitarism or achondroplasia were asked to volunteer for the study. Ninety percent of the persons approached agreed to participate.

The sample consisted of 4 men and 7 women with achondroplasia and 3 men and 2 women with hypopituitary dwarfism. The subjects ranged in age from 19 to 80 years, with an average age of 33 for the dwarfs with achondroplasia and 47 for the hypopituitary dwarfs. The height for both groups ranged from 42 to 57 inches, with an average of 51 inches, which is typical for persons with these disorders (1).

Each subject was seen one or two times in an individual psychiatric interview by one of us (J.S.B.). The interview consisted of a structured portion to obtain certain specific information and a nonstructured portion to allow the development of personal information. The structured portion of the interview included queries into demographic information, aspects of the stress of being a dwarf, and childhood history. Interview data were recorded on a standardized protocol form.

In addition, each subject was given a battery of written psychological tests to be taken home, completed, and mailed back to the examiner. These tests included the Comrey Personality Scales, Shipley-Institute of Living Scale for Measuring Intellectual Impairment, Multiple Affect Adjective Check List, and a modified form of the Draw-a-Person test. On this last test, the subject was asked to draw a picture of himself or herself, then turn the paper over and draw a picture of a normal-sized person.

RESULTS

Since no significant differences were found between the hypopituitary and achondroplastic subjects, results are reported for the total sample.

Marital Status and Living Situations

Eight of the 16 subjects were married and living with their spouses, 3 of whom were of normal size. Four subjects were living with their childhood families, 2 with other adults, and 2 were living alone. Within the total sample there had been one divorce and one annulment of marriage. Fourteen of the dwarfs were living productive lives of employment, school attendance, and/or homemaking. Of the 2 who were not productive, one immature woman was supported by her family, and a man with painful spinal disease was disabled. Four of the subjects were parents.

Childhood Histories

Twelve of the 16 dwarfs had lived in intact families until at least the age of 16, and only 3 of the sample described excessive strife in their childhood families. Four (25%), all with achondroplasia, had one or more relatives who were also dwarfs.

In response to questions about their childhood personalities, 12 (75%) described themselves as happy, 9 (56%) as outgoing as opposed to shy, 8 (50%) as obedient, and 5 (31%) as mischievous. Fourteen of the subjects (88%) described one or more habit disturbances during childhood, including nail-biting (8, or 50%), thumb-sucking (6, or 38%), and enuresis past age 5 (5, or 31%).

All subjects noted that to some extent they had been teased as children. Ten of the 16 (63%) had dealt with the teasing in predominantly passive ways, usually by ignoring it or walking away. Only 6 (38%) had made any sort of an active response, and this was invariably a verbal rather than a physical one.

The majority of the subjects (12, or 75%) remembered liking school, and 10 described themselves as above-average students. Only 2 had failed to graduate from high school, and 8 of the 16 had education beyond the high school level.

Although over half of the subjects (11, or 69%) began dating later than their peers, most of the subjects (11 of 16) eventually made a satisfactory sexual adjustment. Most had at least some dates with people of average height.

Stress Situations Unique to Dwarfism

Nine of the 16 subjects reported that they were not really aware of being different from other people until after they had started school, and some reported no awareness of this until their teens or 20s. Of the 6 subjects to whom the question was applicable, 5 reported no special feelings when a younger sibling passed them in height. Twelve stated that they were treated in accordance with their apparent age, not their actual age.

All agreed that many things in the environment were designed for taller people, and this caused them personal discomfort or inconvenience. Most frequently mentioned were public telephones and shelves in stores. The men commented on the height of urinals in public restrooms.

All of the subjects agreed that job discrimination was a problem. Most felt that it was a combination of the employer's feeling uncomfortable with them and their appearance and the employer's fear that they could not complete the duties of the job because of either their size or intelligence.

All of the subjects were cognizant of the popular expectation that dwarfs are supposed to be "jolly." When questioned about this, all of them gave an answer that approximated, "Some are, some aren't, and some act that way." They did not believe the jolly

quality to be typical and felt that it often represented role playing rather than true feelings.

When questioned about their attitudes concerning children, 9 of the 16 had a firm preference for having short-statured children rather than children of normal height. They cited a variety of reasons for this preference, including difficulties in disciplining a normal-sized child, a greater feeling of identity with a dwarf child, and concern that a normal-sized child would be embarrassed by his dwarf parent. Also mentioned was the somewhat illogical notion that the dwarf parent is better able to help the short child adjust to his height (of course, a normal child would not require such help). The 5 subjects who favored normal-statured children frequently cited less emotionally charged reasons such as, "I'd rather my child not have achondroplasia because people with achondroplasia develop bone and joint disease." Two subjects had no preference regarding this issue.

Exploring the relative merits and disadvantages of proportionate and disproportionate dwarfism, most of both the hypopituitary and achondroplastic dwarfs preferred their own group but thought that each group had certain advantages. The person with achondroplasia was viewed as physically stronger, certain to be sexually mature, and more likely to look his age. The advantages attributed to hypopituitarism included a more attractive physical appearance, greater ease in obtaining clothing that fit, and the increased probability of obtaining jobs in show business. (However, only 3 of the total sample, all hypopituitary dwarfs, were deriving their principal income from show business.) Another advantage of pituitary dwarfism, which was not mentioned by any of the subjects, is that it can be treated if detected early. (There is no treatment for achondroplasia.)

In response to the hypothetical question "Would you accept treatment to make you taller if such treatment existed?" only 3 subjects expressed a willingness to accept such hypothetical treatment, and even they acknowledged that it would create an adjustment problem.

In regard to the overall adjustment to being unusually short, 6 subjects actually viewed shortness as an asset, usually pointing out that it made them "special." Nine dwarfs saw problems in being so short but felt they were able to cope with them. Eleven subjects (69%) identified prejudice and interpersonal difficulties as their major problems, while 5 (31%) were most concerned with physical inconveniences. One dwarf had no opinion on this subject.

Clinical Evaluation

When asked to assess their own mood, 15 of the subjects described themselves as happy or content, and 6 of these qualified their statements by adding that they were occasionally depressed or irritable. One subject described himself as depressed.

On the examiner's assessment all demonstrated appropriate affect. There was no euphoria. There was some evidence of depression in 3 subjects, one of whom also evidenced some anxiety and hostility. None of the subjects was psychotic.

Ten subjects were judged to be mature as evidenced by good judgment, realistic goal formation, effective planning, and adequate self-esteem. Five others were judged less mature because of their greater than usual dependency upon their parents or their continuing interest in issues generally associated with adolescence. One subject with hypopituitarism was grossly immature, with childish speech patterns and self-image. She displayed a clinical picture consistent with 3 cases reported by Spencer and Raft (11).

Ego-defense mechanisms readily identified in the clinical interview or by assessment of behavior included humor, altruism, suppression, and passive-aggressive behavior. These terms are used as described by Vaillant (20). Humor was employed by 13 of the subjects; for example, one of them commented, "The shorter the dwarf, the longer the name of the diagnosis." Thirteen of the 16 used suppression to minimize discomfort; for example, a typical response to a question about what it is like to be a dwarf was, "It's not bad." Altruism was identified in 8 subjects. An example is a high degree of activity in recruiting members for the Little People of America, a self-help organization. Passive-aggressive behavior was noted in 8 subjects. A typical example was a subject who would repeatedly postpone the interviews and then delay returning the psychological test material despite professed interest in and appreciation for the study.

Psychological Testing

Fifteen of the subjects completed the psychological test battery. Because there were completed test materials for only 4 subjects in the hypopituitary group, the 2 diagnostic groups were not compared for statistical significance. Sight evaluation, however, did not suggest any significant differences.

Anxiety, hostility, and depression as measured by the Multiple Affect Adjective Check List indicated that the group as a whole was representative of the general population.

The Comrey Personality Scales compare a variety of personality factors including trust versus defensiveness, social conformity, and masculinity versus femininity, among others. Averaged test scores for these factors indicated that the female dwarfs appeared to be quite average compared with the norms. However, the men had more abnormal scores, and their average was more than one standard deviation from the norm on those scales indicating a tendency toward decreased masculinity, increased conformity, and a tendency to answer questions in a socially desirable manner.

On the modified Draw-a-Person test the subjects correctly perceived themselves as smaller than normal persons and, in fact, they tended to draw themselves as even smaller in proportion to normal persons than they actually were. The average ratio of the subjects'

height to the normal average height was .77, but the ratio of their height to the normal height in the drawings was .72 (where the height of the normal person equals 1.0). Achondroplastic dwarfs have disproportionate bodies. Their heads and trunks are normal-sized while their limbs are considerably shortened because of bone dysplasia. Their heads may appear to be even larger because of frequent frontal bossing. The ratio of the upper body segment to the lower body segment, which in normal persons is slightly less than 1.0, is increased in persons with achondroplasia. The achondroplastic subjects correctly perceived this, drawing the normals with an upper-lower body segment ratio of .96 and themselves with a ratio of 1.27. In addition, the subjects with achondroplasia drew themselves with larger heads than the normals. The ratio of head height to total height was .25 in self drawings and .17 in drawings of normals (where total height equals 1.0). This is consistent with the actual appearance of persons with achondroplasia.

Average IQ, as measured by the Shipley-Institute of Living scale, was 120 for the entire group (125 for the achondroplastic dwarfs and 105 for the hypopituitary dwarfs). These figures must be evaluated with caution since the tests were self-administered, but the clinical impressions did support the finding of above-average intelligence.

DISCUSSION

The degree of psychological well-being and confident self-identity of these adult dwarfs was striking. Their positive adjustment to life despite the stress of a major physical deformity was demonstrated by their ability to maintain productive lives including employment, marriage, and parenthood. Psychological testing confirmed the clinical impression of a relative lack of psychiatric symptoms, excessive anxiety, or depression. A secure sense of identity was suggested by the large number of dwarfs who regarded themselves as "special," would prefer a short to normal-sized child, and who would reject a hypothetical treatment to make them average height. The Draw-a-Person test data confirmed that they had a realistic acceptance of the difference between themselves and others.

We emphasize that what we observed is related to the successful employment of learned coping mechanisms. Our data indicate that as children, the subjects experienced increased inner tension, as evidenced by habit disturbances such as nail-biting and thumb-sucking. They also used denial and repression, as indicated by their failure to comprehend that they were different from other children and their failure to react when a younger sibling passed them in height. Passivity and suppression were used to deal with teasing from other children.

However, by adulthood most dwarfs had learned that the important issue was not their height, but rather the way in which their height affected others. Accordingly, one of the most important coping mechanisms demonstrated was the ability to set others at ease. This was accomplished through a pleasant interpersonal style with frequent use of humor. Participation in the self-help organization, Little People of America (19, 21), assisted some subjects in their identification as a small person and allowed expression of the healthy ego mechanism of altruism. Negative feelings were generally expressed by means of passive-aggressive behavior, and in view of the size differential between themselves and normal people, this appears to be a reasonable solution.

Our finding that adult male dwarfs seemed more disturbed than adult female dwarfs, as evidenced by the results of the Comrey Personality Scales as well as the interviews, can be explained by cultural factors. Masculinity is often symbolized by size and power. Men are expected to be taller than women. The male dwarf finds that not only is he shorter than other men, he is also shorter than almost all women. We hypothesize that it is easier for the female dwarf to accept her shorter stature because it more closely approximates cultural attitudes.

The impression of Money and associates (4, 17) that children with achondroplasia are almost always cheerful and optimistic was not shown to be carried into adulthood. Although many of the dwarfs did appear to be cheerful by either their own report or objective evaluation, this was not felt to be chronic or universal. We suggest that the dwarf's cheerful demeanor is a part of learned coping mechanisms aimed at placing others at ease and therefore facilitating interpersonal relationships. Our data did not support the concept of constitutional euphoria.

The subjects for this study do not represent a random sample of the dwarf population, since we studied only those persons available to us through a medical clinic. It is entirely possible that these people represent a more active and psychologically healthy group and that there are withdrawn and isolated individuals who are not a part of the population from which we could draw.

What is important to stress is that there does exist a sizable group of dwarfs who function well as psychologically healthy and productive members of the community.

Viral Encephalopathy Mimicking Functional Psychosis

BY LAWRENCE G. WILSON, M.D.

Encephalitis, particularly herpes simplex encephalitis, frequently presents as a disorder with puzzling psychiatric symptoms before frank evidence of central nervous system involvement is apparent. The author describes three cases of encephalitis characterized by abrupt onset of bizarre psychological disturbance in the absence of gross neurologic dysfunction. Each patient was initially diagnosed as schizophrenic but later became critically ill and recovered only after a long and chaotic hospital course. The author warns psychiatrists and staff on psychiatric impatient units against mistakenly diagnosing cases of early encephalitis as functional psychoses.

CASES IN WHICH a patient presenting with a psychiatric problem is later found to have an organic illness that may explain the entire clinical picture are common in psychiatry. Herpes simplex encephalitis, the most common form of nonepidemic fatal encephalitis in the United States, frequently presents just this situation. The difficulty of characterizing the symptoms of herpes simplex encephalitis is such that it has been ranked with syphilis as a "great imitator" (1). One review of herpes encephalitis cases (2) reported that all of the adult patients displayed largely psychological symptoms in the early stages of illness, with neurologic symptoms developing later. In another report (3), 10 cases of encephalitis were described in which psychiatric symptoms were the most prominent aspect of the early stage of the illness. Other clinicians have noted that the early course of encephalitis specifically simulates that of a schizophrenic illness (4–6). Weinstein and associates (7) described 6 cases of encephalitis (probably postinfectious type) in which the initial symptoms were very similar to those of many early schizophrenic psychoses. It is of interest that in 4 of the 6 cases severe emotional stress preceded the onset of the disorder.

Thus, patients with this illness frequently are seen by a psychiatrist or admitted to a psychiatric service and diagnosed as having schizophrenia or another psychiatric disorder. Accurate diagnosis of herpes encephalitis is exceedingly difficult (8) and in the past was mainly of academic interest, since supportive care was all that could be offered. With the investigation of several agents (idoxuridine and cytosine arabinoside) that are possibly effective in the treatment of herpes encephalitis (9), differential diagnosis has become more important, since the reported mortality of untreated cases has varied from 50% to 70%. In addition, survivors have frequently suffered neurologic impairment that sometimes resulted in institutionalization. This devastating mortality and morbidity might be substantially reduced if treatment were begun early.

The psychiatrist is sometimes confronted with a patient who responds atypically to treatment for the presumed psychiatric condition but for whom a diagnosis of encephalitis cannot be ruled in or out. Hollander and associates (1) described one case in which neurologists and psychiatrists debated over the diagnosis for a number of days before encephalitis became clearly manifest. In such situations it is important to examine the individual case in detail to determine the presence or absence of differentiating signs of psychiatric and neurologic disease. Even with a detailed family and personal history and adequate physical and laboratory examination, it is often not possible to make a diagnosis. In such cases the patient must be cared for by an interdisciplinary team to give him maximum medical and psychiatric support.

The following 3 case reports demonstrate the difficulties with diagnosis and early management of encephalitis. In all 3 cases, psychiatrists were the key persons involved in management until definite neurologic symptoms developed.

CASE REPORTS

Case 1. The patient was a 30-year-old divorced mother of two who was brought to the hospital by her mother. She was unable to relate a coherent history but did say "I'm crazy—maybe I've been crazy all my life." She said she was "living in a dream" and had felt "unreal" for 2 weeks. The mother said the patient had become despondent and agitated about 2 weeks before and had poor appetite and sleep. She had reportedly lost 10 pounds over this period and had become more disorganized and confused.

The patient had been involved in an affair with her employer and expected to marry him after he was free from his wife. However, several weeks before the patient's admission he had taken his wife and family on an expensive vacation to

Dr. Wilson is Staff Psychiatrist, Veterans Administration Hospital, 4435 Beacon Avenue South, Seattle, Wash. 98108. He is also Assistant Professor, Department of Psychiatry and Behavioral Sciences, University of Washington School of Medicine, Seattle, Wash.

The author is grateful to Drs. Merlin H. Johnson, Donald L. Dudley, and Philip D. Swanson for their help in preparing this paper. He would also like to thank Dr. Donald Farrell, who was the attending neurologist for cases 2 and 3.

the "island paradise" that the patient expected to move to with him when they were married. Her symptoms began at that point, and her mother stated "she acted like her dreams were shattered." She was described as previously being "bull-headed" and "high-strung" but free of major emotional problems. There was no history of psychosis in the family, but there was a history of suicide and alcoholism in previous generations.

On examination the patient appeared frightened and agitated. Formal mental status testing was difficult since her answers to questions regarding time and place were flippant, tangential, or inappropriate. Her speech at times was incoherent, at other times scanty and disorganized. There was no evidence of hallucinations or delusional ideas. She was preoccupied with being "crazy" but later also claimed that everyone was crazy but her. She appeared fearful but responded well to firm direction, relating to the examiner in a childlike manner.

Physical examination disclosed a pulse rate of 104 per minute and normal temperature. The ocular fundi revealed no abnormalities. Neurologic examination was normal with the exception of symmetrically increased deep tendon reflexes. Admission hematologic examination, urinalysis, serum electrolytes, and screening blood chemistry studies were within normal range.

The patient was hospitalized with a provisional diagnosis of acute schizophrenic episode, with seemingly clear-cut precipitating stress in her personal life. She was begun on 400 mg chlorpromazine (Thorazine) per day. After several days of increasing medication she began to display intermittent mutism, staring, exaggerated poses, and immobile postures. This behavior was mixed with babbling and giggling. Medication was further increased after the appearance of waxy flexibility, and ECT was considered because she refused to eat. Ward nurses noticed the patient occasionally "dragging" her right leg, but cursory examination was unremarkable. The patient remained afebrile. On the 10th hospital day she began drooling and later began to choke and aspirate her secretions.

A neurologic consultation was obtained, and the patient was found to have an absent gag reflex and difficulty swallowing but no other specific neurologic abnormalities. An electroencephalogram (EEG) showed a diffusely abnormal pattern compatible with metabolic encephalopathy, with very slow delta wave activity predominating. Chlorpromazine was discontinued and the patient was transferred to the neurology service. The patient was thought to be suffering from an acute metabolic encephalopathy secondary to chlorpromazine or from some type of intracranial pathology with resulting organic brain syndrome.

On the neurology service the initial cerebrospinal fluid examination was normal. Skull films and brain scan showed no abnormality. The patient began to have a mild temperature elevation to 38.5° C (101.3° F) and continued to be agitated and exhibit catatonic signs. She also began to have bizarre, rhythmic tonic and clonic contractions of all extremities that were accompanied by gasping respiratory movements. A second cerebrospinal fluid examination again showed normal chemistry and no cells. The patient developed aspiration pneumonitis and became more severely ill. A third cerebrospinal fluid examination was also normal.

Because of the continuing downhill course and the inability to delineate a specific etiology for the illness, catatonic schizophrenia was thought the most likely diagnosis. While in the intensive care unit the patient was given five electroconvulsive treatments over a 2-day period, with brief improvement after each treatment. ECT was discontinued because of electrocardiographic changes and the development of gram-negative sepsis.

Additional history obtained from the employer revealed that both he and the patient had had symptoms of herpes labialis about 2 weeks prior to her admission to the hospital. She had complained of headache, and psychological disorganization subsequently became obvious. At this time a diagnosis of herpes simplex encephalitis was considered. A fourth cerebrospinal fluid examination (on the 22nd hospital day) showed 30 lymphocytes per mm^3, the first evidence in the spinal fluid of a central nervous system infection (see table 1). Spinal fluid protein and glucose levels remained normal. At the height of the illness a serum antibody titer for herpes simplex virus showed an 8-fold increase, later rising to a 64-fold increase. Viral cultures were obtained, the results of which were not available during the patient's severely ill phase. Herpes simplex virus, presumptive subtype I, was isolated from throat cultures, but cultures of spinal fluid were negative for the virus. Brain biopsy was considered but not done because it was late in the course of the illness. No specific treatment for the encephalitis was given, although the patient did require tracheostomy.

The patient's clinical course gradually improved after the aspiration pneumonitis and gram-negative sepsis were adequately treated. As she became more alert to her surroundings, the unusual bilateral dystonic movements ceased and she became combative and abusive to nursing staff. After further improvement she was returned to the psychiatric service. Motor functions were unimpaired, but she was quite emaciated and weak. At this time the patient was speaking coherently but in a rambling, disjointed fashion, with clang associations and perseveration. She showed confusion and disorientation to time and place but never displayed evidence of delusions or hallucinations. On several occasions she had brief depersonalization episodes, which were apparently precipitated by mildly stressful psychiatric interviews. Her behavior initially was similar to that of a 9-or 10-year-old child and later to that of an early adolescent. Repeated EEGs showed gradual improvement but a continuing generalized abnormality. The patient was given no medication in the recovery phase. She gradually improved in orientation and general behavior and eventually a mild memory defect was the only observable residual of the illness; she was discharged after being hospitalized 3 ½ months.

The patient was seen in follow-up over the next 36 months. Her personal involvement with her employer continued, and she remained hopeful that he would eventually marry her. Follow-up treatment consisted of regular reexamination of neurologic functions and supportive psychotherapy oriented around domestic and romantic stresses. The patient consistently appeared bland and used denial to a rather extreme degree. However, there was never any evidence of delusional thinking, inappropriate affect, hallucinations, or other symptoms suggestive of thought disorder. She had a mild memory defect for the first few months after discharge. She felt that her memory for names and numbers was mildly impaired until about 2 years after discharge, when she felt completely normal. Extensive psychological testing 33 months after discharge gave no evidence of organic impairment. Her psychological profile on the Minnesota Multiphasic Personality Inventory was within normal range.

Case 2. This patient was an adopted 17-year-old high school girl who was transferred to a university hospital from a private community hospital. She had been hospitalized for 7

TABLE 1
Results of Cerebrospinal Fluid Examination in Three Cases of Presumed Herpes Simplex Encephalitis

Patient	Hospital Day	Opening Pressure (mm of water)	White Blood Cells (count per mm³)	Percent of Lymphocytes	Protein (mg/100 ml)	Glucose (mg/100 ml)	Culture
1	12	160	1	100	33	104	Negative
	15	260*	0	—	20	76	Negative
	20	150	—**	—	24	88	Negative

*** Within normal limits.

days because of the acute onset of bizarre behavior and subsequent lethargy and mutism. The referring psychiatrist believed that catatonic schizophrenia was the diagnosis but sought neurological consultation before consideration of ECT.

The patient had been in good health and had been an active competitive swimmer in high school. There was no history of psychiatric illness in the patient or her adoptive family. She had begun acting bizarrely 3 days before admission, when she began taking notes on family conversations and television programs. She also made many uncharacteristic comments and at times had garbled speech. This sort of worrisome behavior occurred intermittently over a 3-day period. After experiencing chills one night and claiming that "Satan is taking me over," she was taken by her parents to a hospital for evaluation.

Complete records from the first hospitalization are not available. The patient was diagnosed as having an acute psychotic reaction and was initially treated with 7 mg of haloperidol (Haldol) and .5 mg of benztropine mesylate (Cogentin) per day. After several days she became dysarthric and later became mute. Her mother noticed her "limping" with her right leg, "like she'd had a stroke." After continuing this deteriorating course and spiking a fever to 38.9° C (102° F), she was transferred to the university hospital psychiatric service.

Examination showed an uncommunicative young girl who followed the examiner with her eyes but produced only gutteral sounds and occasional garbled speech. Temperature was 38.9° C (102° F) and pulse was 100. Pupils were equal and reactive and the fundi were benign. She showed increased muscle tone of the right extremities and intermittent clonus of the right ankle. Plantar reflexes were flexor. There was a maculopapular rash of the perioral region with some vesicles present. Further history from the parents revealed that the patient had been troubled with a rash on the chin and perioral area for about 1 month.

The patient was transferred to the neurology service immediately after initial examination. An EEG showed very severe generalized disturbance of brain function. A spinal tap revealed normal opening pressure, no white cells, 7 red cells, and normal protein and glucose values. Brain scan and echoencephalogram were normal, as were initial hematologic, serum chemistry, and urine values. In spite of the normal spinal fluid findings, the patient was thought to be suffering from herpes simplex encephalitis. However, a brain biopsy was negative for cell changes typical of herpes, and multiple cultures of spinal fluid, brain, pharynx, and rectum failed to recover any viral, bacterial, or fungal agent. Serological tests for a wide variety of viruses (including herpes, Coxsackie, influenza, mumps, and cytomegalic inclusion virus) showed no titer rise indicative of infection.

The patient continued on a downhill course, at first receiving only supportive care. She developed aspiration pneumonitis but responded to antibiotic therapy. Four additional diagnostic spinal taps showed small numbers of mononuclear cells but normal glucose and protein values (see table 1).

After several weeks of hospitalization, the patient was more responsive to her environment, smiling and reacting to her doctor's comments. Gradually she began speaking recognizably, but repeated words or phrases in an echolalic fashion. She was transferred to a rehabilitation unit where she continued to improve her moderately impaired motor skills. Therapy with 300 mg of diphenylhydantoin (Dilantin) daily was begun because of the appearance of epileptic foci in the EEG. When she was discharged after a total of 60 days' hospitalization she was able to follow simple commands and take care of her personal needs with supervision. She continued to speak in a rambling and irrelevant fashion and was quite distractible in a childlike manner.

After the patient returned home she required close supervision but continued to improve. She pursued her swimming interests and returned to high school, where she received above average grades. She continued to manifest short-term memory disturbance and occasional impulsive behavior 6 months after discharge. Follow-up EEG at 6 months showed continuing abnormalities in both temporal regions. The

patient gradually regained almost complete recent memory function, graduated from high school with a "B" average, and began college. An EEG 16 months after discharge showed only very mild abnormalities.

Case 3. The patient was a 20-year-old unmarried male who lived with his parents. He had been in good physical health until he "passed out" while with a girlfriend at a bowling alley. He was described as having a "spaced-out" appearance, with some possible seizure activity. There was incontinence of urine and a suggestion of head-turning to the right. He expressed fears of being poisoned or "possessed" by his girlfriend.

The patient was hospitalized on a neurology ward of a military hospital for investigation; while there he had probable minor seizures. While hospitalized he had a normal neurological examination, normal EEG, and normal brain scan. He was discharged after several days with only phenobarbital prescribed. In the 24 hours after discharge, he displayed bizarre behavior, disorientation and inappropriate laughing and crying. He also apparently showed clumsiness of his right hand and had some perseveration of motor movements.

The patient was readmitted to the neurology service and extensive investigation was undertaken. A brain scan, two EEGs, and blood and liver chemistry studies were normal. A lumbar puncture showed elevated opening pressure (270 mm of water versus a normal of under 170 mm), but the spinal fluid smears and cultures were negative. The patient's behavior continued to be bizarre, with babbling and incoherence. He was transferred to the psychiatry service after 10 days on the neurology service because a definite neurologic diagnosis could not be made. A diagnosis of catatonic schizophrenia was made, and treatment was begun with chlorpromazine, haloperidol, and benztropine mesylate.

In spite of doses of haloperidol up to 80 mg per day, the patient's behavior deteriorated. He became delusional and claimed he was dead; later he claimed that the devil was in possession of him. He began to show posturing and would hold his extremities in unusual fixed positions for long periods of time. He later became "stuporous," holding his body in an opisthotonic position. Because of the development of pneumonitis, his inability to take food, and the continuing downhill course, he was transferred to a nearby university hospital for electroconvulsive therapy of the presumed catatonic schizophrenia.

On arrival at the university hospital psychiatric service, the patient had a temperature of 38.4° C (101° F). He would occasionally open his eyes and make brief eye contact but was unresponsive to verbal or painful stimuli. The neck was rigid in a mildly extended position and the legs rigidly extended. There was clonus of the right ankle and the gag reflex was absent. The patient was transferred to the neurology service. He began to have prolonged seizures of a temporal lobe status epilepticus type that were very difficult to control. There were no localizing signs on neurological examination and the EEG was suggestive of encephalitis.

Subsequent lumbar punctures (see table 1) showed increased opening pressure and small numbers of lymphocytes. Spinal fluid cultures were negative for bacteria, viruses, and cryptococcus. Another brain scan was normal, as was an echoencephalogram. Tests for porphyria were negative. Serologic tests for a large variety of viruses did not indicate current infection. However, the attending neurologist considered herpes simplex encephalitis the most probable diagnosis. Brain biopsy was considered but was not performed.

The patient developed severe pneumonitis and needed a tracheostomy to control secretions. His seizures were finally brought under control but rigid muscle tone and waxy flexibility remained. However, he became more responsive to the environment and after about 30 hospital days he was able to walk and talk. His intellectual and motor function slowly returned and after about 45 hospital days there were no specific motor, sensory, or reflex deficits. The patient showed very poor short-term memory and decreased intellectual function compared with his pre-illness state. He was transferred to a rehabilitation service for work with his minor speech deficits and to await a return of his short-term memory functions. He remained only on anticonvulsant medications. He was discharged after 2 months of hospitalization to a special school program. An EEG 3 months after discharge was essentially normal, but at 5 months after discharge there was still definitely decreased short-term memory function.

DISCUSSION

Encephalitis has long been noted to produce psychological disorganization in its early stages. As in these 3 cases, differential diagnosis is usually difficult, with signs of brain disease frequently being ambiguous, late, or both. The importance of early diagnosis is clear from these cases. All 3 patients developed probable aspiration pneumonitis and 2 required tracheostomies, which earlier intensive nursing care (usually not available on a psychiatric ward) might have prevented. Intensive medical management of the commonly associated cerebral edema (for example, with corticosteroids) might prevent some of the morbidity of the illness. Although idoxuridine was recently reported to be both ineffective and severely toxic in a large interhospital study (10), early diagnosis may also allow the use of some specifically effective drug agents.

These cases demonstrate the need to continually reevaluate the patient with presumed psychiatric illness who responds atypically to psychiatric management during hospitalization. Once a patient is diagnosed as having a psychiatric problem, ward staff frequently tend to minimize observations that ordinarily indicate organic dysfunction. In our cases the previously diagnosed psychiatric conditions diminished the impact of observations like "limping" and "dragging a leg." In any psychiatric patient with vague or soft neurologic signs or mild disturbance of sensorium (no matter how well explained by supposed severe psychiatric illness) careful observation should be the watchword. The most underutilized of the psychiatrist's techniques, the mental status examination, should be carefully repeated in these cases. This procedure alone would often indicate the neurologic nature of the disorder early in its course. In all of our cases, the severe disturbance in sensorium would probably have become more obvious and the "thought disorder" less impressive with serial testing. Repeated neurologic examinations and special neurologic tests (EEG, brain scan) add another diagnostic dimension. In addition, an amobarbital (Amytal) interview has been found to be valuable as an aid to differentiating

psychiatric from neurologic disorders (11, 12). In catatonia, amytal will usually result in the patient's beginning to talk, and psychotic speech or delusional ideas will become obvious. In encephalitis or other brain disease, the neurologic or communication deficits will usually become more prominent.

The difficulty with diagnosis in our cases was compounded by the late development of evidence of infection in the spinal fluid. Normal spinal fluid findings until the 15th or 20th hospital day are unusual but not unknown in cases proven by brain biopsy to be herpes encephalitis. All 3 cases were diagnosed as catatonic schizophrenia; 2, both before and after neurologic consultation and work-up, and 1 before neurologic consultation. One patient received ECT after intensive neurologic investigation was inconclusive. The 2 others were referred to the university hospital for ECT for their presumed catatonia; both were immediately recognized on admission as having probable neurologic disease. One case had serological evidence (64-fold increase in antibody titer) and positive throat culture for herpes; the other 2 cases had clinical evidence of herpes encephalitis but no specific laboratory evidence. Two of the 3 patients became very seriously ill, with mixed coma and seizure states. All had very slow recoveries with recent memory disturbances many months after discharge. All 3 patients had the same team of attending neurologists involved in their cases and it was their consensus that herpes simplex encephalitis was the most likely diagnosis.

Another problem in the differential diagnosis of encephalitis is the frequent occurrence of psychological or social stress factors in the patient's life. Often these will appear to the examiner to be precipitating causes of a functional psychosis. Patient 1 particularly draws our attention to this factor, since her symptoms began at a time of severe personal disappointment. Did she experience an acute psychotic reaction and *then* develop encephalitis, or did she develop a psychosis during the prodromal phase of her central nervous system viral infection, with the romantic disappointment being merely an interesting, but chance, concurrent event? It is often assumed that the onset of organic illness is related to physical conditions, whereas the onset of psychiatric illness is related to life change or life stress. However, there is increasing evidence (13) that both psychiatric and medical illnesses become manifest during major life changes, disturbing life events, or certain psychological states such as depression. Schmale (14) found 41 of 42 unselected hospitalized patients with medical illness to have evidence of loss (either actual, threatened, or symbolic) and feelings of hopelessness and helplessness prior to the onset of the disease. In another study, Greene and his colleagues (15) found that a high percentage of persons who died suddenly and unexpectedly had been previously depressed.

Some recent work (16) has strongly linked stress, emotions, and immunity. The immunosuppressive qualities of adrenocortical hormones, whose levels are responsive to stress, may be important in the pathogenesis of infectious illness. A variety of viral infections have been related to stress in animals. Certain frustrating laboratory situations have caused increased susceptibility to herpes simplex infection in mice (17, 18). A clinical finding related to this was made in a group of patients with psychotic depression (19). This group had significantly higher levels of antibody to herpes simplex virus as compared with a group of persons with other psychiatric disorders and healthy controls. The investigators considered the possibility that the herpes infection might disturb brain chemistry and lead to depression. They did not, however, consider the possibility that depression and its associated endocrinologic changes might predispose to increased infection with the ever-present herpes virus. Another group has suggested that brain changes as a result of mild or inapparent herpes infection of the central nervous system may result in pathological conditions that lead to aggressive psychopathic behavior. In a small group of patients, Cleobury and associates (20) found that psychopathic persons had higher levels of serum antibody to herpes virus type 1 than patients with other psychiatric disorders or control patients in a general hospital. Thus, there is some evidence that a combination of stress and exposure to virus (or a latent carrier state) may lead to encephalitis and that the impact on behavior of even mild infection may be considerable.

The 3 cases presented illustrate that frequently a diagnosis of schizophrenia is made for an acutely psychotic patient without careful consideration of alternative explanations. It is becoming clear that more than a cross-sectional view of a person is needed for this diagnosis. Some recent work on diagnostic criteria in psychiatry (21) has suggested that the clinician must consider presenting picture, past functioning, and family history before making a diagnosis of schizophrenia. Too quick a reliance on a diagnosis of schizophrenia often precludes further investigation of the etiology of a psychotic state.

Although cases of sporadic encephalitis are infrequent, psychiatrists must be careful to investigate fully any case of psychosis that does not follow a typical course. Inpatient psychiatric staffs must make careful observations to detect at an early stage those cases of encephalitis which initially present as psychiatric disturbances.

Prompt Publication Policy

The *Journal* would like to remind authors who are particularly interested in early publication (whether to establish priority of an idea, reveal innovative results of new research, or for other pressing reasons) of its prompt publication policy. Under this policy, short (maximum of six double-spaced pages) manuscripts will be considered for publication in the Brief Communications section of the first available issue. These manuscripts must still undergo expert scrutiny before being accepted, and two months must be allowed for the printing process. However, the time required for publication of these short articles can be lessened considerably.

Authors who would like to have their manuscripts considered under this policy should indicate this desire, as well as the reasons for it, when they submit their manuscripts.

Introduction

BY RICHARD JED WYATT, M.D.

SINCE THE SCHIZOPHRENIC syndrome was first described around the turn of the century, there have been many false starts at defining its symptoms, course, and etiology, as well as determining the best way to treat it. While most observers believe the syndrome to be real, extremely painful, and debilitating, our knowledge has not advanced proportionately to the efforts we have made. The Symposium on Current Concepts of Schizophrenia held at the 128th annual meeting of the American Psychiatric Association was designed to present reviews of some of the many current areas of investigation in schizophrenia.

My reaction to the symposium was that, although we do not yet have the answers, our techniques, understanding of experimental controls, organization of research, and general objectivity are advancing rapidly.

Dr. Carpenter describes a diagnostic method that may eventually be used internationally. The method is based largely on current symptoms and signs, but he suggests that longitudinal information is also needed for more rigor. Dr. Kohn's review of the literature on social class indicates that schizophrenia occurs most frequently in the lowest social classes, a finding that can probably be considered a fact at this time. The reasons for this relationship are not yet known definitively; however, Dr. Kohn presents interesting hypotheses.

Dr. Reiss' review of family studies leads him to conclude that there are abnormalities in the interaction of families of schizophrenics and that these abnormalities may precede the onset of the disorder. While it is not yet clear what role these abnormalities play in the etiology of the illness, Dr. Reiss proposes methods for examining this role and recommends rapprochement and joint endeavor as an alternative to the relatively entrenched schism among the social, psychological, and biologic approaches to the study of schizophrenia.

Perhaps the major research advances have come from adoption studies, which demonstrate the importance of genetic factors in the etiology of schizophrenia. Drs. Matthysse and Kidd use mathematical models to assess the magnitude of the genetic contribution—a question that the studies of adoptees and twins have not answered. They conclude that the figure may exceed 47%, a percentage derived from the concordance rate for monozygotic schizophrenic twins.

Dr. Meltzer imaginatively and diligently follows up an observation that creatine phosphokinase (CPK) is transiently elevated in the serum of acutely disturbed psychotic patients. While intramuscular drug injections and nonspecific factors such as activity or stress may account for some of the increases, they cannot account for the majority. The functional significance of this finding, particularly in light of the fact that increased CPK activity is present in both schizophrenia and the affective disorders, is not known. However, Dr. Meltzer's work demonstrates a systematic methodology for examining such an observation.

Dr. Snyder reviews the most exciting current hypothesis of schizophrenia: that the schizophrenic behaves as if there were an excess of dopamine in the brain. The evidence is circumstantial at this point, but information generated from investigations in this area is rapidly expanding. Drs. Gillin, Kaplan, Stillman, and Wyatt review criteria by which biochemical hypotheses of schizophrenia can be tested. To illustrate the application of these criteria, they examine the short-acting hallucinogen, *N,N*-dimethyltryptamine (DMT), which meets some but not all of the investigational criteria. Finally, Dr. Davis, who frequently uses the library as his laboratory, provides us with some new ways to look at the neuroleptic drugs.

Of course, there are other important areas of recent investigation of schizophrenia that could not, because of space limitations, be represented in this symposium. There has been much research on the level of the

Revised version of remarks presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Wyatt is Acting Chief, Laboratory of Clinical Psychopharmacology, Bldg. 10, Rm. 4N206, National Institute of Mental Health, 9000 Rockville Pike, Bethesda, Md. 20014.

enzyme monoamine oxidase in the platelets of chronic schizophrenic patients (1–4), the controversy over megavitamin therapy has received considerable attention (5–8), and there have been investigations of disordered cognition and perceptual defects in schizophrenics, including studies of visual scanning differences between schizophrenics and normal individuals (9, 10). Abnormalities in reaction time (11) and histamine metabolism (12) are not being as actively examined now as they have been in the past, but they remain fairly secure associated abnormalities of the disorder.

The statistical, psychological, physiologic, and biochemical tools for understanding schizophrenia may be in our hands, but we will know this only in retrospect. It is clear from the papers in this section, however, that these tools are becoming extremely powerful—a final example is the incredibly increased capabilities of such research methods as mass spectrometry. In the meantime, in order to be honest, we must say to our patients and our readers, "We don't know yet—but we *are* working on it."

Current Diagnostic Concepts in Schizophrenia

BY WILLIAM T. CARPENTER, JR., M.D.

The diagnosis of psychiatric disorders currently relies primarily on clinical observation and evaluation of manifest psychopathology. Symptom-based diagnosis of schizophrenia defines a highly variable patient population and thus makes replication of research results difficult. However, this diagnostic approach is useful because it has established communicative value, encourages clinicians to rely on the diagnostic data most readily available (i.e., the patient's behavior), and relates directly to treatment plans. The author describes a 12-point symptom-based diagnostic system for schizophrenia that enhances the reliability and (presumably) validity of the diagnostic process. He then illustrates methods that can be used to select homogeneous schizophrenic populations for specialized research purposes.

FOCUSING ON current diagnostic concepts of schizophrenia is both simple and complex. It is simple because nosologic concepts of the functional psychoses have undergone relatively modest alterations over the past few decades. We now, as always, rely heavily on manifest psychopathology (catalogued as signs and symptoms) for diagnosis. The diagnostic process is built on clinical observation—the foundation of scientific medicine.

The weakness of present techniques for identifying schizophrenic patients is several-fold and relates to validity, reliability, and the meaning of manifest psycho-

Dr. Carpenter is Director, Schizophrenia Research Programs, Department of Psychiatry, Albert Einstein College of Medicine, Bronx Municipal Hospital, Eastchester Road and Pelham Parkway, Bronx, N.Y. 10461.

pathology. In these areas matters become complex. To date we have had few validating criteria for the diagnosis of schizophrenia (1–3), and those validity criteria presently applicable would fail to identify many patients diagnosed schizophrenic, even when stringent criteria are used for the diagnosis (1, 2, 4). Poor diagnostic reliability has also often been demonstrated (5–11).

The most critical limitation in using manifest psychopathology to identify schizophrenic patients, however, is that symptoms are not the disease itself. We know that some characteristic symptoms of schizophrenia may be highly discriminating, but they are not pathognomonic. Furthermore, aspects of schizophrenia have been observed in nonschizophrenic persons with organic psychosyndromes, including those induced by drugs. That symptoms are not the disease itself is, of course, a truism. It is important to note only because the etiology and pathogenesis of schizophrenia are largely unknown, and ancillary diagnostic tools such as laboratory tests are not yet available. Since nosology and treatment of schizophrenia relate so directly to the patient's manifest behavior, and since the search for etiological clues often focuses on variables that alter (by either inducing or reducing) symptoms, it is worth keeping in mind that a patient's accusing hallucinations may relate to schizophrenia the way a tubercular patient's cough relates to his disease. Schizophrenia is an imperfectly defined syndrome that encompasses patients with different etiologies, divergent pathogeneses, various treatment requirements, and heterogeneous outcomes.

Despite these problems and others (e.g., the negative attributes of labeling a person schizophrenic [12–17]), I believe there is ample evidence that the inclusion of schizophrenia in our nosology carries far more useful information than misinformation. The other papers in this section, for example, document important associations between a schizophrenic diagnosis and communication styles in families, status in society, family history of schizophrenia, some biologic variables, and pharmacologic responsivity.

SIGNS AND SYMPTOMS AS DIAGNOSTIC CRITERIA

Recent methodologic advances have encouraged a fresh look at the symptom criteria for schizophrenia. These advances can be simply stated. 1) Structured clinical interview techniques can now be used to reliably and systematically assess manifest psychopathology in large numbers of patients (18–20). 2) Computer and mathematical techniques enhance the identification of critical diagnostic variables. Analysis of variance, discriminant function analysis, factor analysis, cluster analysis, and other programs can be applied to large bodies of data to evaluate old and seek new diagnostic information. 3) Factors such as differential psychopharmacology, family history of major psychoses, and platelet monoamine oxidase activity have emerged as potential validating criteria for the diagnosis of schizophrenia.

Rather than review the current literature, I will illustrate the application of these methodologic advances in one study (21) that was conducted under the auspices of the International Pilot Study of Schizophrenia (IPSS). The choice of this study is justified by several attributes of the IPSS—large sample size, systematic and reliable data collection, and use of patients and psychiatrists with diverse backgrounds.

The IPSS is a transcultural psychiatric investigation of 1,202 patients in nine countries: China, Colombia, Czechoslovakia, Denmark, India, Nigeria, the Union of Soviet Socialist Republics, the United Kingdom, and the United States. It was designed as a pilot study to lay scientific groundwork for future international epidemiologic studies of schizophrenia and other psychiatric disorders. Details of the methodology employed in this investigation are provided elsewhere (20).

The material to be reviewed relates to a specific question: what signs and symptoms can best distinguish schizophrenic patients from other severely disturbed psychiatric patients? For practical clinical and research purposes, operational criteria for diagnosing schizophrenia are essential. Schneider's diagnostic model is a suitable paradigm (22, 23). Following this model, we approached our data atheoretically (with no etiological assumption). We wished to find highly discriminating symptoms of schizophrenia that occurred frequently enough to have practical application and that could be reliably assessed by observing clinicians. Such symptoms, taken together with other relevant diagnostic data (e.g., history), could provide a basis for reliable and replicable diagnosis.

The Present State Exam (PSE) was used by investigators in each of nine centers to rate signs and symptoms in recently admitted patients with evidence of psychosis. Patients with organic psychosyndromes and those who were chronically institutionalized were excluded. This study design selected 1,202 patients, 811 of whom were diagnosed as schizophrenic by the interviewing psychiatrist, based on manifest psychopathology during the past month (Present State Exam), history and social descriptive data obtained using other research instruments (20), and any other information available to the psychiatrist. Eighty-three of the 1,202 patients (6%) were dropped because they could not be clearly assigned to either the schizophrenic or nonschizophrenic group (e.g., those with paranoid states). The remaining 1,119 patients were randomized into two cohorts, each containing about 405 schizophrenic and 155 nonschizophrenic patients. Cohort B was omitted from the initial data analysis and held in reserve to replicate or refute findings in cohort A. The 230 symptoms and 130 signs of the PSE were arranged as 443 overlapping variables, including single items and psychopathologic dimensions formed by combining related signs and symptoms.

These methods illustrate one recent advance in study techniques—systematic and reliable collection of behavioral data for substantial numbers of selected patients. A second advanced technique used in the IPSS study was the application of mathematical techniques with computer assistance. We have reported elsewhere the results of evaluating several established and experimental diagnostic systems (24–26). I will review only the system that most effectively separated diagnosed schizophrenic patients from nonschizophrenic patients in cohort A and was replicated in cohort B.

An analysis of variance (ANOVA) program was applied to the 443 variables, yielding the discriminating power of each variable taken alone. Using the ANOVA results as a guide, the less discriminating variables in groups of obviously overlapping variables were eliminated. This resulted in 69 significant discriminating variables ($p<.01$ for each). Data from the two groups of patients (schizophrenic and nonschizophrenic) were then subjected to a stepwise discriminate function analysis based on these 69 variables. The first step in the discriminate function run showed diagnostic assignments based on the single most discriminating symptom from the ANOVA (restricted affect). The second symptom added was chosen for its power to increase discrimination between the schizophrenic and nonschizophrenic groups, given knowledge of the first symptom. Thus, symptoms were added stepwise by taking into account the symptom information already included. Appendix 1 lists the 12 most discriminating symptoms, ranked in order of their appearance on the stepwise discriminate function program, as well as PSE items associated with each symptom and their reliability.

This 12-point system is designed to be applied as a unit. The 9 signs and symptoms more prevalent in schizophrenia are scored 1 point each if present, while the 3 symptoms—waking early, depressed facies, and elation—more prevalent in the nonschizophrenic group are scored 1 point each when absent. Thus, the most stringent criteria for a diagnosis of schizophrenia would be a total score of 12 (i.e., 9 schizophrenic symptoms present and 3 nonschizophrenic symptoms absent).

The effectiveness of this system is shown by table 1. A meaningful split between schizophrenic and nonschizophrenic diagnostic assignments results when one determines that at least 5 points are present. A substantial number of diagnosed schizophrenic patients would be judged schizophrenic and relatively few of the patients assigned nonschizophrenic diagnoses would be relegated to the schizophrenic group by these criteria. The percentages in the top (schizophrenic) row can guide the clinician as to the applicability of this system to a schizophrenic population. For example, he might expect 80% of acute and subacute schizophrenic patients to have at least 5 of these symptoms. In the second (nonschizophrenic) row, the percentages indicate the degree of error one might anticipate when making diagnostic assignments with this system. For example, if a patient with 5 or more of these symptoms is assigned automatically to a schizophrenic category, one would expect about 13% of diagnosed nonschizophrenic patients to be assigned to schizophrenic groups.

TABLE 1
Results of a 12-Point System Used to Differentiate Schizophrenic and Nonschizophrenic Patients

Percent of Patients	Number of Points		
	5 or More	6 or More	7 or More
Cohort A			
Schizophrenic patients (N=407)	80	66	44
Nonschizophrenic patients (N=152)	13	4	1
Cohort B			
Schizophrenic patients (N=404)	81	63	39
Nonschizophrenic patients (N=156)	22	6	1

This 12-point system was derived from cohort A and thus worked well with those patients. The results in cohort B (table 1) represented a replication study, since these patients did not contribute to the derivation of the system. A chi-square comparison of the results in cohorts A and B revealed no difference ($p<.4$), and examination of table 1 indicates similar effectiveness of the 12-point system in both cohorts.

This 12-point symptom-based diagnostic system can be used at different levels of stringency, for each of which the number of false-positive inclusions can be estimated. The system is based on reliable data, its effectiveness has been replicated, and it is sufficiently brief to be readily taught and applied.[1]

BEYOND SIGNS AND SYMPTOMS

The 12-point system for identifying schizophrenic patients presented above has considerable potential for increasing diagnostic reliability. Even so, there is little reason to expect a homogeneous patient group to emerge from its application, regardless of how stringent the symptom criteria, because we have little reason to think that schizophrenia, as presently defined, is a single illness. The evidence for this can be readily surmised from reports dealing with genetic and biologic factors in schizophrenia (1, 2, 4, 28–30). There are

[1]Methodologic details and a more complete discussion of this system are given elsewhere (21). Also discussed elsewhere are the questions why 12 symptoms are better than 11 and as good as 13 or 14, and how this system compares with other systems. An evaluation of extant subtypes of schizophrenia and a proposal for new subgroups are presented in an article now in press (27).

thus a number of theoretical and practical limitations to the use of symptom criteria for schizophrenic diagnois. Symptoms are not etiologic indicators (i.e., if substance A induces symptom remission, schizophrenia cannot be said to be caused by the insufficiency of substance A), and symptoms do not define a homogeneous population regarding genetics, function, outcome, and treatment.

Strauss (31, 32) has proposed a multi-axial diagnostic model that would include social functioning and course of illness along with symptoms as diagnostic criteria. Each of these three axes would be conceptualized along a continuum. There are a number of other axes that can enter a nosologic scheme, depending on the aims of classification. Some examples of these diagnostic dimensions are: 1) signs and symptoms, 2) course and outcome, 3) social functioning, 4) work functioning, 5) psychiatric history, 6) family history of mental disease, 7) pharmacologic responsivity, 8) biochemical/psychophysiologic variables, and 9) communication patterns in families.

For example, if it is desirable for a diagnosis to predict outcome, then prognostic variables must be added to symptom criteria, since symptoms alone (with the probable exception of defect or negative symptoms [e.g., flat affect]) do not define a homogeneous outcome (33, 34). If diagnostic consistency over time is desired, then psychiatric history variables could be used to exclude patients with previous nonschizophrenic diagnoses. If the aim of diagnosis is to identify schizophrenic patients for a study of psychological factors, it might be desirable to use stringent symptom criteria in combination with evidence for a communication defect in the family and an absence of schizophrenia in biologic relatives.

The immediate practical value of a multidimensional diagnostic approach can be illustrated by its application to investigations of the role of biological factors in schizophrenia. Many investigators are currently studying biological variables in schizophrenia, an area of study greatly reinforced by findings in Danish adoptive studies and by increased knowledge of the mechanism of neuroleptic drug action. Until recently, failure to replicate biologic findings was almost routine (35), and inability to select comparable patients for study in various centers no doubt played a role. Recent biologic work, such as that by Dr. Meltzer in this section, is more satisfying but still far from adequate (30). A major problem resides in the failure to adequately define biologically homogeneous subgroups of schizophrenia, let alone describe patients sufficiently to permit others to select similar patients. This variation in patients can be reduced by applying current knowledge of schizophrenia. An investigator could begin by considering for study patients clinically diagnosed as schizophrenic. This large and heterogeneous population could then be narrowed by applying the 12-point symptom criteria system and including only patients with, for example, 6 or more points. Next, patients with histories suggesting a nonschizophrenic mental illness would be excluded, reducing the number of false positives. Criteria for poor social functioning prior to the current episode of illness can be specified and applied (34, 36) and would result in a patient cohort relatively homogeneous in symptom and social functioning status. This population could be further reduced by requiring a family history of schizophrenia, thus increasing the genetic loading. The final result would be a small but far less variable group of patients suited for biological investigations.

The criteria described above are clinical variables, but laboratory variables may also soon be useful in sorting out subgroups of schizophrenia. For example, sharply reduced platelet monoamine oxidase (MAO) activity may be associated with a genetic vulnerability for chronic schizophrenia (3), but MAO activity appears to be normal in good-prognosis acute schizophrenic patients (4). Holzman has similarly hypothesized that impaired smooth pursuit in eye tracking may separate potentially chronic schizophrenic patients from those with a good prognosis (37).

CONCLUSIONS

Nosology provides a foundation for scientific psychiatry—systems of classification are essential for the acquisition of information and generation of hypotheses. Kraepelin and Bleuler made landmark contributions in defining the diagnostic class now called schizophrenia, but progress in nosology since 1911 has been relatively modest. We continue to identify patients as schizophrenic based primarily on signs and symptoms, but even when well-defined and stringent criteria are used we have a heterogeneous patient population in terms of genetics, biochemistry, psychology, environment, treatment, course, and outcome. This variability results partly from the absence of readily available diagnostic validation (e.g., laboratory tests) and partly because the schizophrenic syndrome is probably comprised of several illnesses not yet teased apart and identified.

Despite this confusing and at times discouraging picture, there is abundant rationale for using sign and symptom criteria in defining schizophrenia. It is traditional and thus has established communicative value. Diagnosing with signs and symptoms uses the backbone of modern medicine—clinical observation; it thus encourages conceptualizing mental illness in terms of the information at hand, i.e., the patient's manifest behavior. Furthermore, symptom-based diagnosis relates directly to the treatment process, since symptoms rather than pathogenesis appear to be the most frequent targets of treatment.

I have reviewed one system that can enhance the identification of schizophrenic patients when used in the clinical diagnostic process. This system, even when its most stringent criteria are applied, will not define a homogeneous clinical entity. Other clinical or laboratory dimensions may, however, be applied to

the diagnostic process to select increasingly homogeneous populations for specialized purposes.

APPENDIX 1

A 12-Point Diagnostic System

The following items from the Present State Examination (19, 20) correspond to the signs or symptoms of a 12-point diagnostic system for identifying schizophrenic patients. (r=reliability; (–) indicates that absence of the criterion favors a diagnosis of schizophrenia.)

1. *Restricted affect:* Blank, expressionless face (r=.62); Very little or no emotion shown when delusion or normal material is discussed which would usually bring out emotion (r=.63)
2. *Poor insight:* Overall rating of insight (r=.85)
3. *Thoughts aloud:* Do you feel your thoughts are being broadcast, transmitted, so that everyone knows what you are thinking? (r=.95); Do you ever seem to hear your thoughts spoken aloud? (Almost as if someone standing nearby could hear them?) (r=.74)

4. *Waking early* (–): Have you been waking earlier in the morning and remaining awake? (rated positive if one to three hours earlier than usual) (r=.83)
5. *Poor rapport:* Did the interviewer find it possible to establish good rapport with patient? (r=.86); other difficulties in rapport (r=.75)
6. *Depressed facies* (–): Facial expression sad, depressed (r=.73)
7. *Elation* (–): Elated, joyous mood (r=.67)
8. *Widespread delusions:* How widespread are patient's delusions? How many areas in patient's life are interpreted delusionally (r=.74)
9. *Incoherent speech:* Free and spontaneous flow of incoherent speech (r=.74)
10. *Unreliable information:* Was the information obtained in this interview credible or not? (r=.73)
11. *Bizarre delusions:* Are the delusions comprehensible? (r=.69)
12. *Nihilistic delusions:* Do you feel that your body is decaying, rotting? (insufficient variability to determine reliability); do you feel that some part of your body is missing, for example, head, brain, or arms? (r=.70); do you ever have the feeling that you do not exist at all, that you are dead, dissolved? (r=.71)

The Interaction of Social Class and Other Factors in the Etiology of Schizophrenia

BY MELVIN L. KOHN, PH.D.

Epidemiological evidence clearly indicates an especially high rate of schizophrenia at the lowest social class levels of urban populations. The author suggests that this relationship between class and schizophrenia exists because the conditions of life experienced by people of lower social class position foster conceptions of social reality that are so limited and rigid as to impair their ability to deal resourcefully with the problematic and the stressful. Such impairment does not in itself result in schizophrenia; however, in conjunction with genetic vulnerability and great stress, it could be disabling.

IN THE LIMITED space available, I shall attempt to summarize the evidence on the aspect of the social environment that has most consistently been shown to be related to schizophrenia—social class. Since this evidence has been thoroughly reviewed in the literature (1–3), I shall not review it here, but instead assess its strengths and weaknesses. I will focus on the questions of how social class enters into the etiological process and how we can develop causal models that take account of the contributions of social class, genetics, stress, and other variables whose pertinence to schizophrenia has not yet been established.

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Kohn is Chief, Laboratory of Socioenvironmental Studies, National Institute of Mental Health, Bldg. 10, Rm. 3D54, 9000 Rockville Pike, Bethesda, Md. 20014.

This paper is based in substantial part on a more extensive discussion (1) which provides the documentation that is lacking in this brief overview of the issues.

CLASS AND SCHIZOPHRENIA

I will use social class to mean, essentially, position in the hierarchical ordering of society, usually indexed by occupational position or by some combination of occupation and education. There have been more than 50 studies of the relationship between social class and rates of schizophrenia. Almost without exception, these studies have shown that schizophrenia occurs most frequently at the lowest social class levels of urban society. The evidence comes from research conducted in Canada, Denmark, Finland, Great Britain, Norway, Sweden, Taiwan, and the United States—an unusually large number of countries and cultures for establishing the generality of any relationship in social science. Moreover, the exceptions to this established relationship are few and incomplete: they occur in small cities and rural areas or in special subpopulations of larger cities, and none contradicts the larger generalization of an especially high rate of schizophrenia at the lowest social class levels of urban populations. What is not clear is *why* class is related to schizophrenia.

Some argue that the statistical relationship between social class and rates of schizophrenia is only artifactual, the result of methodological error. The princi-

pal issues are the adequacy of indices, the completeness of search procedures, and the relative merits and defects of incidence and prevalence as appropriate statistical measures. Although these issues are not entirely resolved, the very fact that numerous studies using many different research methods have all come to the same conclusion argues strongly that the class-schizophrenia relationship is not just a statistical artifact.

Others accept the statistical relationship but assert that schizophrenics are found disproportionately in lower social classes because of the impairment they have suffered or because of some characterological defect of nonsocial origin. The social status of schizophrenics, from this point of view, tells us something about how they fare in society but little or nothing about what produces schizophrenia.

The evidence on this issue is far from unequivocal, but it seems to me that the bulk of it argues against this hypothesis providing a *sufficient* explanation of the class-schizophrenia relationship. In all probability, families from the lower social classes produce a disproportionate number of schizophrenics, although not by so large a margin as one would conclude from studies that rely on schizophrenics' own occupational attainments.

Still other interpretations emphasize the processes by which people come to be perceived as mentally disordered and what consequently happens to them. One point of view holds that psychiatric and other authorities are especially prone to stigmatize and hospitalize people from the lower social classes. Other explanations focus on the processes by which families, employers, police, and others come to label some deviant behaviors as mentally disordered, thereby setting in motion complex changes in social expectation and self-concept that may result in hospitalization. In this framework, social position matters not because of its role in producing the initially deviant behavior but because it affects other people's perceptions of and reactions to that behavior. The class-schizophrenia relationship thus is seen to document the discriminatory readiness of many people to see signs of mental disorder in lower-class behavior.

There is little solid evidence to support this interpretation; some evidence indicates that this approach is based on assumptions that are inconsistent with what is known. A principal rebuttal stems from the evidence that people strongly resist seeing deviant behavior as mentally disordered, attempting to interpret even grotesque behavior as somehow normal and situationally explainable.

Many interpretations of the epidemiologic data accord primary causal significance to processes that are only tangentially or incidentally related to social class position itself. These interpretations emphasize such processes as social isolation, social integration, discrepancies between aspirations and achievements, and minority position in the community, to name but a few. All of these interpretations are plausible, and most are consistent with existing data. However, there is no reason to favor any of them over the most straightforward interpretation possible, i.e., that social class is related to schizophrenia primarily because the conditions of life built in to lower social class position are conducive to this disorder.

There are several reasons why this might be true: people in lower social classes live in more stressful conditions, they have little money or power to employ in coping with the consequences of stress, there are fewer institutional resources available to them for escaping stressful situations or mitigating the consequences of stress, and lower-class conditions of life limit individuals' internal resources for dealing with stressful or problematic situations. These are not incompatible interpretations; they are all plausible and, as yet, untested. These hypotheses become particularly interesting when examined in conjunction with genetics and stress.

GENETICS OF SCHIZOPHRENIA

Since the evidence for the etiologic role of genetics in schizophrenia is reviewed elsewhere in this section, I will note only that I believe recent studies of monozygotic twins and adopted children demonstrate beyond any reasonable doubt that some genetic mechanism must be involved in the etiology of schizophrenia. One might argue, in fact, that genetics explains the relationship between social class and schizophrenia. If there is a heritable component in schizophrenia, there must have been higher than usual rates of the disorder among the parents and grandparents of schizophrenics. Since schizophrenia is debilitating, there would also have been downward social mobility in these earlier generations. Thus schizophrenics could come disproportionately from families in lower social classes not because the conditions of life they experience have pernicious effects, but rather because there is a concentration of genetically susceptible people in the lower social classes.

That such processes occur is indisputable, but a detailed analysis of rates of intergenerational occupational mobility of schizophrenics makes it seem highly unlikely that class differences in the incidence of schizophrenia result entirely—or even largely—from genetically induced intergenerational social mobility. Thus genetics cannot totally explain the class-schizophrenia relationship.

STRESS AND SCHIZOPHRENIA

The evidence for the role of stress in the etiology of schizophrenia is much less clear-cut than that for social class or genetics, but it is sufficient to establish a prima facie case. Although I am aware of no definitive study in this area, there are pertinent studies that indicate an association between stress and the occurrence of schizophrenia. One important study (4) in-

dicated that the relationship between stress and schizophrenia does not simply reflect the high levels of stress prevalent in the lower social classes. This investigation of schizophrenics and matched controls in the lowest social class of San Juan, Puerto Rico, showed that during the year before the onset of symptoms, the schizophrenics experienced notably greater stress than the controls. Even when judged by the harsh standards of life of the San Juan slums, the stresses that preceded the onset of schizophrenia were unusually severe.

As with genetics, we must ask whether stress explains the relationship of class to schizophrenia. Unfortunately, the only study that has provided data for all levels of social class assessed mental disorder in general rather than schizophrenia in particular (5). This study is nevertheless germane because it showed that at any given level of stress, people of lower social class position are more likely to become mentally disturbed than are people of higher social class position. In fact, the more sources of stress there are, the greater the class difference in the proportion of people who manifest psychotic symptoms. The implication is that the relationship of class to mental disorder (and, if we may extrapolate, to schizophrenia) is not attributable to the amount of stress that people endure. There must also be important class differences in how effectively people deal with stress.

THE INTERACTION OF GENETICS, STRESS, AND SOCIAL CLASS

On the basis of the discussion thus far, we can summarize three essential facts about the current state of our knowledge of the epidemiology of schizophrenia:

1. There is abundant evidence that social class is related to schizophrenia but considerable uncertainty as to why.
2. There is abundant evidence that genetics is involved in the etiology of schizophrenia but much uncertainty as to how.
3. There is enough evidence to make it seem likely that stress is also involved, although we are not yet certain of this.

An implicit but certainly important observation is that none of these three factors can possibly account for schizophrenia except in combination with one or both of the other two and perhaps other, as yet unknown, factors.

The evidence that none of these factors alone can account for schizophrenia is clear and results from the research in each individual area. The incidence of schizophrenia in the lowest social class, although higher than that in other social classes, is low by any absolute standard, certainly less than 10% no matter what measurements are used. Similarly, the concordance rate for monozygotic twins of schizophrenics, although higher than that for dizygotic twins and for siblings, is much less than 100% and probably less than 50% in the more carefully executed studies. Also, the incidence of schizophrenia among people subjected to even the most heavy bombardment of stress in their daily lives is probably not very high by absolute standards, although in this case the evidence is too limited to estimate absolute magnitude.

These facts argue that the explanation of schizophrenia lies in the interaction—the joint occurrence—of genetic predisposition, stress, and the conditions of life associated with social class. I think it would be profitable for us to begin to develop theoretical models that attempt to take account of such interactions.

A PROPOSED INTERACTIVE MODEL

I have designed a formulation that I chose because I think it is plausible, potentially testable, and offers a good illustration of the type of interpretive model that we should begin to develop.

I suggest that the constricted conditions of life experienced by people of lower social class position foster conceptions of social reality that are so limited and so rigid as to impair their ability to deal resourcefully with the problematic and the stressful. Although such impairment is unfortunate, it would not in and of itself result in schizophrenia. However, in conjunction with a genetic vulnerability and the experience of great stress, such impairment *could* be disabling and result in schizophrenia.

This formulation is admittedly speculative. However, it is a direct extrapolation from what is known about the relationship between social class and conceptions of reality (6). The lower an individual's social class position, the more likely he is to value conformity to external authority and to believe that such conformity is all that his own capacities and the exigencies of the world allow. In particular, the lower a person's social class position, the more likely his orientational system is to be characterized by a rigidly conservative view of man and his social institutions, by fearfulness and distrust, and by a fatalistic belief that he is at the mercy of forces beyond his control and often beyond his understanding.

The existence of these class differences in beliefs and values is hardly accidental, nor is it cultural in the sense employed by "culture of poverty" theorists, who believe that lower-class orientations are handed down from generation to generation independently of current social conditions. In actuality, social class embodies such basic differences in conditions of life that subjective reality is necessarily different for people differentially situated in the social hierarchy. Lower-class conditions of life allow little freedom of action and give individuals little reason to feel they control their fate. To be in a low social class is to be insufficiently educated and to work at a job of little substantive complexity under close supervision, with little possibility of varying the routine flow of work. These are precisely the conditions that narrow one's concep-

tion of social reality and reduce one's sense of personal efficacy.

Thus there is ample evidence that class differences in conditions of life produce differences in conceptions of social reality. But do these differences in orientation contribute to the class-schizophrenia relationship? There are three reasons for thinking that they might.

1. Instead of searching aimlessly among the innumerable correlates of social class for one that might help explain its relationship to schizophrenia, I think it is strategic to look to something that is fundamental to the social psychology of class: that members of different social classes, by virtue of enjoying (or suffering) different conditions of life, come to see the world differently—to develop different conceptions of social reality, different conceptions of the desirable, and different aspirations, hopes, and fears. Class differences in orientation are an important bridge between social conditions and psychological functioning.

2. My brief review of the literature on the epidemiology of schizophrenia points to the desirability of considering any factor that might bear on class differences in people's effectiveness in dealing with stressful or problematic situations. It seems to me that the orientational system characteristic of the lower social classes is less adequate for dealing with such situations than that of the higher social classes. Admittedly, the characteristic lower-class orientational system, molded as it is by actual conditions, may often be useful, in that it provides a defensive strategy for people who truly are vulnerable to forces they cannot control. However, there are times when a defensive posture invites attack and the assumption that one is at the mercy of forces beyond one's control—although justified—leaves one all the more at the mercy of these forces. An orientational system predicated on conforming to the dictates of authority results in a perception of social reality that is too simplistic and fearful to allow the individual to take advantage of options that might present themselves. It is too inflexible to permit effective coping with precisely those problematic and stressful circumstances that most require subtlety, flexibility, and a perceptive understanding of larger social complexities.

3. Orientations—conceptions of reality—are a fundamental aspect of schizophrenia: fearful, inflexible reactions to threat are integral to the schizophrenic experience. One reason for the disproportionately high incidence of schizophrenia at lower social class levels may be that schizophrenic disorders build on conceptions of reality firmly grounded in the experiences of these social classes.

My proposed formulation thus attempts to bring genetics, stress, and the conditions of life related to social class position into one coherent interpretation of schizophrenia. The thrust of the argument is that the conditions of life experienced by people of lower social class position tend to impair their ability to deal resourcefully with problematic and stressful situations. This impairment, occurring in conjunction with a genetic vulnerability to schizophrenia and the experience of great stress, could be disabling. Since both genetic vulnerability and stress appear to occur disproportionately at lower social class levels, people in these segments of society may be in triple jeopardy.

Whether or not this particular formulation will prove to be the key to the puzzle of schizophrenia, it does illustrate a type of interpretive model more adequate to the complexities of the current and rapidly accumulating evidence than the earlier models. These models tried, unsuccessfully, to attribute schizophrenia to a single causal variable—genetics, family relationships, social class, stress, etc. An interactive model of the type I have proposed can deal with the evidence that no one factor explains schizophrenia and that some combination of relevant conditions must be present to cause schizophrenia.

Testing any theoretical model based on the hypothesis of interactive relationships among causal variables requires a different mode of research from that ordinarily used in studying schizophrenia. This mode should include the study of genetic, psychological, and social factors in the same research designs. Although this will not be easy, it is counterproductive to continue to examine social class, stress, and genetics in separate studies as if they were additive or as if any one of them could in itself explain schizophrenia.

The Family and Schizophrenia

BY DAVID REISS, M.D.

The author discusses the role of the family in the etiology of schizophrenia and suggests how this research might be integrated with our growing knowledge of the biology of schizophrenia. Abnormalities of family interaction–particularly communication deviances–are frequently associated with schizophrenia and may play a causal, rather than epiphenomenal, role in its pathogenesis. Communication processes in family life affect the child's development of attentional and perceptual capacities, which also have strong biologic roots. The author suggests that the study of normal and abnormal perceptual development might be a meeting ground for researchers in the areas of the biological and familial theories of schizophrenia.

THE LAST DECADE has been full of exciting advances in the study of schizophrenia, and this special section represents a sampling of these new findings. Although the data are new, this group of papers displays the familiar Cartesian split: two papers represent the Cartesian "mind," now called "psychosocial variables," and most of the other papers represent the "body," now given such labels as "genetic mechanisms," "creatine phosphokinase," and "synaptic transmission." This dualism reflects the structure of our field, which in turn reflects the continuing dualism of our conception of mental illness and human development. Each of us must develop proof of the validity of our variables and their specific role in the etiology of schizophrenia. We have applied to this work a set of increasingly rigorous scientific standards that seem only to have increased the austerity and solitude of our pursuits. Why should we not now enjoy some of the fruits of our work by joining our efforts in an attempt to formulate a unified concept of the evolution of schizophrenia?

In this brief review of the role of the family in the etiology of schizophrenia, I will present first my opinion of how far our field, working in relative isolation from other areas of investigation (chiefly biologic), has advanced in proving the etiologic role of the patient's family and then speculate on how this work on the family might relate to the biologic investigations.

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Reiss is Professor, Departments of Psychiatry and Behavioral Sciences and of Medicine, George Washington University School of Medicine, 2300 I St., N.W., Washington, D.C. 20037.

RECENT RESEARCH ON FAMILY VARIABLES IN SCHIZOPHRENIA

The role of the family in the etiology of schizophrenia can be assessed by the same general scientific principles as the role of biologic variables. First, the hypothesized variables must be clearly defined and measured by reliable and objective methods. Second, the causal role of the variable must be assessed by demonstrating that it 1) is specifically linked with schizophrenia as opposed to other conditions and states, 2) has an impact on the individual before the onset of schizophrenia, and 3) is not confounded with a covarying or concomitant variable that is the "true" etiologic variable.

I will discuss the relevant work that has been done in each of these areas and the research strategies that have been developed to carry out this work.

Identification and Measurement

The major impetus for family research in the area of schizophrenia was the early work of Theodore Lidz at Yale University, Gregory Bateson at the Mental Research Institute, Palo Alto, Calif., and Lyman Wynne at the National Institute of Mental Health. Mishler and Waxler (1) have critically reviewed these ground-breaking concepts.

Lidz' work stimulated interest in two aspects of relationships between the parents of the schizophrenic—the quality of their emotional ties and the relative power of the parents. Lidz found intense discord and distrust in the marital relations of parents of schizophrenics, particularly females. He also suggested that in the case of male schizophrenics, the father is abnormally submissive and the mother is abnormally dominant. In recent years a variety of techniques has been developed to measure affective quality and power balance in marital relations.

Bateson and Wynne, on the other hand, stimulated interest in communication between parent and child. Bateson noted profound logical inconsistencies in the communications of parents of schizophrenics, and Wynne observed blurring, fragmentation, and disqualification in communication. In response to these early observations and ideas, researchers have developed a variety of measures of clarity of speech, the capacity of family members to understand one another,

and the quantity of information and flexibility in verbal exchanges.

Many of these variables meet scientific standards reasonably well. They are all assessed by direct, quantitative measurement of family interaction, often in well-controlled laboratory settings. A few of these measurements meet quite exacting psychometric standards: they possess concurrent, discriminatory, and predictive validity, as well as adequate interrater reliability and stability over time. Unfortunately, there have also been weaknesses in these variables. Particularly in their application to actual studies, they do not match the sophistication or complexity of the theories from which they are derived. This is particularly true for those measuring conflict, dominance, and affect. A second weakness is that the variables depend too heavily on rater judgments: an independent judge observes a family interacting, listens to a tape, or codes a typescript and then scores the family. These judgments, however reliable, leave too much room for bias and subjectivity. Riskin and Faunce (2) have reviewed problems of validity and reliability in family interaction research methods.

In the past few years there have been some exciting new trends in identifying and measuring family variables that have not yet been systematically applied to schizophrenia. However, I believe they are fully applicable. I will briefly mention two of them. The first trend resulted from the application of ethology and structural linguistics to family life, which has stimulated an interest in the structure of rules each family seems to develop for itself over time. These rules govern the family's relationships with other families and the wider social community. Both clinical and laboratory evidence indicates that families of schizophrenics have peculiar or idiosyncratic relationships with the wider social community. Our laboratory has reported one method for assessing these relationships: repeated measurements of families interacting with one another in a multiple family group (3). A second trend is the increasing recognition that behavior of family members during family interaction is tightly coordinated on a microscopic level. For example, Condon and Ogston (4) observed that during a dinner table conversation the movement of every individual was carefully regulated by the phonemic structure in the speech of the family member who was talking. These and many similar observations suggest a vast unseen continent of family interaction processes completely invisible to the unaided observer and measurable only with precise instruments in laboratory situations. It seems entirely possible that the most devastating and enduring influences of the family may be manifest on this microscopic level of family interaction.

Controlled Study of Family Variables as Etiologic Factors

Specific, concurrent links between family and schizophrenia. Despite substantial advances in the identification and measurement of family variables, their specific links to schizophrenia are modest at best (5, 6). The results in the areas of power, affect, and conflict have been inconsistent. For example, some studies have shown more evidence of abnormal affect in normal families than in families of schizophrenics; others have reported just the reverse. Studies of parental submissiveness have generally been inconclusive. However, studies of communication clarity have yielded consistently reproducible results. More than 20 separate studies in at least 10 different laboratories have demonstrated that communications between parents of schizophrenics and one or another of their children are blurred, poorly understood, inconsistent, poorly focused, wandering, disruptive, and illogical. The difference between families of schizophrenics and those of normal individuals is often large. More important, this abnormality of family communication seems specifically linked to families of schizophrenics and occurs much less frequently, if at all, in families that include individuals with other serious psychiatric disorders such as impulsive character disturbances. These findings seem reproducible in a variety of conditions; for example, several findings from middle class families can be replicated among lower class families, and findings with well siblings repeat those with the identified patient present.

The time of impact of family variables. There are two fundamentally different explanations for the finding that family abnormalities are regularly associated with schizophrenia. The first is that the family abnormalities precede the schizophrenic disorder (and presumably are one of its causes). The second is that the onset of schizophrenia may come first; in that case, abnormal communication might represent the family's response to the disorganizing impact of the schizophrenic member. To my knowledge there have been three approaches to assessing these alternatives: experimental models, follow-back and follow-up studies, and longitudinal studies.

In the experimental model, investigators have tried to shorten drastically the time course of the evolution of schizophrenia. They have introduced experimentally an abnormality in either parental or sibling interaction and observed the impact on the normal children and parents, respectively. For example, Haley (7) exposed normal children to audiotapes of parents of schizophrenic children, and Waxler (8), in a problem-solving experiment, included two groups of pseudo-families (parents and child drawn from different families), one with parents of schizophrenics and a normal child and the other with parents of normal children and a schizophrenic child. In our laboratory, we used secobarbital to induce a temporary thought disturbance in an offspring and observed the impact on family interaction (9).

In the follow-back studies, school or clinic records of schizophrenics from periods before they were overtly ill are compared with similar records from control subjects. Little data on families are available from these studies. In the follow-up study, the 20- to 30-year

old records of contrasting groups of children are located and compared. A search is made for these adults and the follow-up data in terms of psychopathology are correlated with the childhood records (10–12).

In the longitudinal studies (there are two in progress focusing particularly on the family) a high-risk sample of children is identified and followed for some years (6). Family and other variables are measured at regular intervals. These variables are correlated with later pathologic outcome.

The findings from the longitudinal studies are just becoming available. Findings from the laboratory model and follow-up and follow-back studies have been published in the last few years. The combined evidence suggests that a number of the family abnormalities are unlikely to be a consequence of (i.e., occur after) the onset of the schizophrenia. The basic pattern of evidence suggests that family abnormalities exist before the onset of the illness. Not all of these studies examined communication in families. Haley (7) and Reiss (9) studied some of the specific communication variables that seem so promising at present, whereas Ricks (10) and Waring (11) reported the establishment of more global family abnormalities, such as symbiotic relationships and withdrawal of the family from the community in the years before the onset of schizophrenia.

Separation from confounding variables. Even if we can ascertain that a family abnormality (e.g., a communications deficit) precedes the onset of schizophrenia, we cannot say that it is either a necessary or sufficient cause of schizophrenia. It is entirely possible that abnormalities in parental behavior reflect an underlying, preclinical genetic disturbance in which case schizophrenia in the offspring would be the result of genetic transmission. Disturbed communication would in this model be considered epiphenomenal, not causal. In other words, genetic and family variables may be confounded because they covary. Through the years, there have been many attempts to disentangle these two variables. Most scholars in the field agree, however, that this has only been possible in the last 8 years since the publication of the Oregon and Danish adoption studies (13–16.) Most family researchers who have carefully reviewed the data from the earlier studies regard them as strong support for the role of a genetic mechanism. We did not, however, believe they provided strong evidence for or against the necessary or sufficient role of family variables. A more recent report from the Danish adoption studies, specifically investigating family variables, demonstrates a small but distinct role for family variables. Rosenthal and associates (17) found significant correlations between disordered family relationships and pathologic outcome in adoptees whose biologic parents were not schizophrenic. This suggests that family abnormalities may produce a pathologic outcome in the absence of pathogenic genes but may have no appreciable effect when the genes are present. However, this finding is limited by the design of the study, which required the investigator to recreate the early family life of adoptees from their comments and recollections as adults.

Major Research Strategies

Each of the three separate groups of investigators has a very special role to play in the elucidation of the family's role and its relationship to other variables (including the biologic one). The *cross-sectional group* use laboratory and other precision methods for measuring interaction processes in families with a schizophrenic member. They usually conduct measurements during a single time period. Their two distinct tasks are identifying variables that are likely correlates of schizophrenia, which requires the development of careful and comprehensive theory as well as precise and reliable methods, and systematically testing the specific relationship between these variables and schizophrenia. They note distinctions between various subtypes of schizophrenia and contrast family patterns associated with schizophrenia with those associated with other psychiatric syndromes, other nonpsychiatric disabilities, and with those in families whose members are physically and mentally healthy. Their work has yielded and should continue to yield variables specifically linked with schizophrenia or one of its several subtypes.

The investigators who conduct *adoption studies* use two basic approaches: either the parents are directly observed (e.g., Wender [16] compared parents biologically related to a child who becomes schizophrenic, parents raising an adopted child who becomes schizophrenic, and parents raising adopted children who remain healthy), or the adopted children are studied. Rosenthal (17) and Heston and Denney (13) compared children who had different biologic and rearing experiences; for example, the mental health of a group of adoptees whose biologic parents were schizophrenic was compared with a group whose biologic parents were healthy. Recently, a third comparison group of children has been added—adoptees whose biologic parents were healthy but whose adopting parents were schizophrenic (18). In the study of adopted children, the parents are rarely (if ever) available for direct study. Thus the investigator must depend on the adopted offspring (usually an adult at the time of the study) to reconstruct his/her childhood from memory.

Those investigators who conduct *longitudinal studies* follow the course of children and their parents from a period of time before the child became schizophrenic. In order to improve the chances of finding schizophrenics in their sample, these investigators select children at risk (i.e., either their parents are schizophrenic or the children display some suspicious abnormality). These researchers are in a unique situation in that they can determine the time of onset of schizophrenia and observe whether it precedes or follows the family abnormalities. They have the special role of determining how successfully an investigator, by using data available after the disorder has appeared, can reconstruct

the family life of a schizophrenic before the disorder was developed.

There is an important system of exchanges between the three groups of investigators. The consistent correlates found in the cross-sectional studies can be used in the longitudinal and the adoption studies. Because these variables require direct observation of parents, they cannot be extended to the studies of adopted children. However, the longitudinal studies can determine which of the consistent correlates hold up over time and which can be reconstructed by other means (e.g., retrospective accounts by adults of their childhood). These purified variables become most salient for studies of adopted children.

POSSIBLE RELATIONSHIPS BETWEEN FAMILY AND BIOLOGIC VARIABLES

We need some assurance that the purified variables that may emerge from a conglomerate of cross-sectional, longitudinal, and adoption investigations relate in some way to a general conception of schizophrenia that can integrate both biologic and social findings. I shall focus on the communication abnormalities, which have proved to be consistent family correlates of schizophrenia. According to present odds, if you like to wager, these are the family variables most likely to emerge from the multi-design studies as a consistent correlate of schizophrenia, as preceding its onset and as a necessary etiologic agent for at least a subset of the schizophrenias. In relating these findings to biologic studies, I will make one major assumption—that biologic and family abnormalities will be found in the same population of schizophrenics (i.e., that we do not have a situation in which biologic variables, without influence from family variables, produce one subset and family abnormalities, unrelated to biologic factors, produce another quite distinct subset).[1]

Parental communication patterns serve in a very fundamental way to shape and mold the basic perceptual functions of young children. Clear parental communication patterns tend to highlight and amplify the child's stimulus world; they vividly convey the breadth and variety of the parent's experience of his own existential universe (19–21). As research by Mishler and Waxler (22) strongly suggests, flexible communication patterns permit the child to insert his own percepts and observations into the family interaction when he is ready. Ambiguous and inconsistent parental communication patterns blur the stimulus world for the growing child. He is unable to grasp his parents' experience of the world and his own experience is often disqualified and undercut (23). Inflexible communication patterns between his parents may prevent him from presenting his own observations to others or requesting help. We can understand, then, how family interaction patterns—particularly the communication variables so specifically linked with schizophrenia—can have a profound effect on the growing child's capacities and styles for processing stimuli: his attentional capacities and his styles or habits of regulating stimulus intensity and of integrating, differentiating, and giving meaning to stimuli. I emphasize these elementary capacities and styles of stimulus processing because recent evidence has indicated that there may be very specific deficits in these processes that underlie many, if not most, of the cardinal symptoms of schizophrenia (24, 25). Furthermore, these psychological processes have strong biologic roots: they seem to have a genetic component (26), they can be studied with biologic tools such as the average evoked response (27, 28), and they can be altered by psychotropic drugs (29). Thus these elementary psychological processes of stimulus processing are important intervening variables. As we purify family variables to determine their etiologic significance in schizophrenia, we should pay special attention to their influence on these elementary perceptual processes. Biologic investigators may benefit from the same strategy; they can examine the relationship between measurements of enzymes, synaptic physiology, and neuropharmacology on the one hand with assessments of elementary perceptual processes on the other. Wyatt and I have discussed such a strategy in detail elsewhere (30). The fundamental point is that the Cartesian split is poor scientific strategy. "Mind" and "body" researchers need to join forces and find variables both can love. Schizophrenia may be conceptualized as a special form of human development shaped by deficits or distortions of specific and elementary psychologic variables that (according to present evidence) are vulnerable to both social and biologic influence. The perceptual variables that I and others have emphasized may not be the final meeting ground for psychosocial and biologic investigators, but they do permit a strategy worth pursuing.

[1]Rosenthal's recent research (17) does not, in my view, seriously challenge this assumption because of the methodologic limitations of his study.

Estimating the Genetic Contribution to Schizophrenia

BY STEVEN W. MATTHYSSE, PH.D., AND KENNETH K. KIDD, PH.D.

The authors discuss the limitations of the concept of heritability in schizophrenia and, using reported incidence figures, assess two alternatives—the multifactorial and single major locus (SML) models. Both models predict genetic heterogeneity in schizophrenia. For some parameter values, the SML model indicates that homozygotes are rare but at very high risk. According to the multifactorial model, 9.1% of the schizophrenic population has a genetic risk of 99% or more. The authors conclude that neither model adequately accounts for the data but that predictions from both can be used to design sampling procedures which will increase the probability of selecting for study individuals whose illness is highly genetically determined.

STRONG EVIDENCE for genetic factors in the etiology of schizophrenia has been provided by adoption studies (1), but the mode of transmission and the extent of genetic determination are still unknown. Since not all identical twins of schizophrenics are also schizophre-

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

nic, nongenetic events must have some influence; however, it is not known whether these events are pre- or postnatal, psychosocial or physical.

The concept of "heritability" has often been used to estimate the magnitude of the genetic contribution, but this term has semantic and mathematical ambiguities. Although the dictionary definition of heritable as "capable of being inherited" is unobjectionable, the geneticist uses a different and more precise definition. First, the total variation of a trait within a population (measured as the variance) is divided into genetic and environmental components and a component representing their interaction. The genetic component is then further divided into "additive" and "dominance" effects. The distinction between the latter components is best understood by recalling that each individual has two alleles (genes) at each locus, one from each parent. If one form of the gene is pathogenic and the other is not, an individual can be genetically normal at the locus, heterozygous (single dose of the pathogenic allele), or homozygous (double dose). If the effect of a single dose is exactly half that of a double dose, the allele is said to be additive. Otherwise, there will be dominance variation as well as additive variation. Thus heritability in the genetic definition (symbolized by h^2) is the proportion of a trait's variation in the population that is due to additive genetic variation among individuals.

LIMITATIONS OF THE CONCEPT OF HERITABILITY

In its precise form, the heritability concept has several limitations.

First, the heritability of a trait depends on the range of relevant environmental variation in the population being studied. If the population is subjected to a wider range of environments, heritability will decrease; conversely, if the relevant aspects of the environment are held constant, heritability will increase. Furthermore, it frequently happens that the range of environments in the sample studied is not representative of the general population, so the heritability estimate cannot be safely extended to the population as a whole. In fact, drug therapy and psychotherapy can be considered as novel environments so that, logically speaking, one would have to conclude that the heritability of schizophrenia changed when these modalities were introduced.

A second limitation is that heritability requires quantitative definition of a trait. When there are several different ways of defining a trait (as is always the case in psychiatry), there will be several different heritability estimates. Gottesman and Shields (2) first applied the multifactorial model of Falconer (3) to schizophrenia and obtained a heritability estimate of about 80%. The attribute to which this heritability applies is not actually a measured trait; it is a hypothetical underlying, continuous, and normally distributed variable called "liability." One can also calculate heritability for schizophrenia defined as an all-or-none trait (i.e., arbitrary discrete scores for normal and affected individuals). With this definition of the attribute, heritability would be placed at 20%–40% for a single-gene model. It is also possible to construct a single-gene model with an underlying continuous liability that is not normally distributed (4, 5); heritability of the liability scores is in the range of 0%–15%. Thus, three different definitions of the trait result in three different heritabilities.

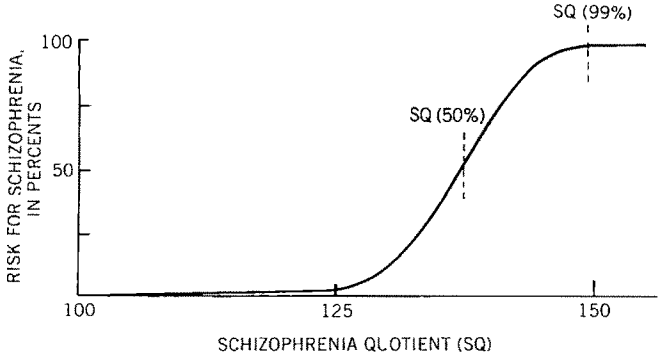
The third problem is that in order to calculate heritability, it is necessary to assume that genetic and environmental components contribute additively to the trait, that they are not correlated with each other (6, 7), and that the rearing environment is not dependent on whether the parents have the trait. When there is "cultural transmission," as in learning a language, the last assumption certainly breaks down.

In summary, heritability does not provide information on etiology, is not able to predict response to novel environments, and cannot be unambiguously estimated from data. Therefore, it is our conclusion that heritability of schizophrenia is not a meaningful concept or statistic, even though the disease has a clear genetic component.

THE SINGLE MAJOR LOCUS AND MULTIFACTORIAL MODELS

A more satisfactory approach to estimating the genetic contribution to schizophrenia begins by adopting a specific model of transmission. After fitting the parameters of the model to the data as well as is possible, the relative contribution of genetic factors is estimated within the context of the model. The major limitation of this approach is that we do not yet have enough information to decide among the alternative models. Nevertheless, one can select two extreme genetic models and estimate the genetic contribution in terms of each of them.

The single major locus (SML) and multifactorial models are among the simplest that incorporate both genetic and environmental factors; they are both frequently encountered in the study of human genetics. These models represent the genetic extremes of "monogenic" and "polygenic" inheritance. It is known that nongenetic factors can mimic genetic and even Mendelian inheritance (8). Such influences as children's learning a trait from their parents or from imitation of their siblings (e.g., language and dietary preferences), are called "cultural inheritance." Neither model specifically incorporates cultural transmission. Although the multifactorial model would allow culturally transmitted factors, they would not be separable from the genetic factors. Thus environmental influences are assumed to be randomly distributed for both models. This assumption may not be too restrictive, since there is no compelling evidence for cultural transmission in schizophrenia (9).



The SML model has four unknown parameters that must be estimated from the data (10): 1) q, the fre-

quency of the pathogenic allele (the form of the gene that increases the risk for schizophrenia) in the general population; 2) f_0, the probability that an individual who is genetically normal nevertheless becomes schizophrenic at some time in his life (these individuals are called "phenocopies" because they have the phenotype without the genotype); 3) f_1, the probability that an individual with one pathogenic allele at the "schizophrenia locus" and one normal allele (a heterozygote) develops the disorder; and 4) f_2, the probability that an individual with two pathogenic alleles at this locus (a homozygote) becomes schizophrenic. The parameters f_1 and f_2 are sometimes called the penetrances of the allele in the heterozygous and homozygous state. When $f_1 = f_0$, the allele only has an influence when it is present in double dose, and the trait is said to be recessive. When $f_1 = f_2$, the heterozygote has just as high a risk as the homozygote, and the trait is said to be dominant. Intermediate cases in which $f_0 < f_1 < f_2$ are also possible; in such situations the terms "dominant" and "recessive" are not applicable and can be misleading.

The multifactorial model represents an opposite extreme. Genetic vulnerability is assumed to be caused by the action of a large number of independent genes; no one genetic factor predominates, but each contributes a small amount to the risk. Intelligence is thought to be a trait of this kind, and the analogy with IQ can be very helpful. The IQ score is derived by scaling test results so that the scores will have a normal (i.e., bell-shaped) distribution in the general population, with a mean of 100 and standard deviation of 15. We can postulate the same kind of scale for vulnerability to schizophrenia (although we do not have a test to measure it) and call it the schizophrenia quotient (SQ). SQ will also be scaled to have a normal distribution in the general population, with a mean of 100 and standard deviation of 15. For each value of SQ, there is a certain lifetime risk for schizophrenia. SQs well below 100 are associated with a risk near 0, while SQs well above 100 are associated with a risk near 100%. Continuing the analogy with IQ, the risk is like the probability that an individual with a certain IQ will graduate from college. The normal distribution curve for SQ in the population is not an assumption—like IQ, the variable is scaled in such a way that it has to be normal—but the shape of the risk function is an assumption. In the multifactorial model the postulated risk function is a cumulative normal (or sigmoid) curve (11) as illustrated in figure 1. The sigmoid shape for the risk function is plausible, but there is no special empirical justification for it; it is really chosen for mathematical convenience. There are two unknown parameters in the cumulative normal risk function: its position on the SQ axis and its steepness. These can be determined in several ways, for example, as is indicated in figure 1, by the values of SQ associated with 50% risk and with 99% risk.[1]

It is important to make a distinction between vulnerability to schizophrenia (SQ) and "schizoid personality." A person who is genetically vulnerable to schizophrenia may never develop either schizophrenia or schizoid personality if the environment is favorable. Conversely, some schizoid individuals may maintain their dubious adjustment for a lifetime without becoming schizophrenic. Indeed, Pollin (12) was impressed that the identical twins of schizophrenics who do not themselves have the illness are not rated as more schizoid than individuals not related to a schizophrenic.

FIGURE 1
Risk Function for the Multifactorial Model

ESTIMATION OF PARAMETERS

Having defined the two extreme genetic models, let us try to fit their parameters (q, f_0, f_1, f_2 in the monogenic model; SQ(50%) and SQ(99%) in the polygenic model) to the data on schizophrenia. The data we have available are primarily the frequencies with which schizophrenia occurs among the relatives of a diagnosed schizophrenic. Published reports of these frequencies are unfortunately not fully consistent (4), and the estimates cannot be combined in any rigorous way because the studies were carried out under different conditions using different criteria for schizophrenia. For concordance rates in identical twins (IMZ), we have used an average based on five recent studies (those of Gottesman, Kringlen, Fischer, Tienari, and Pollin) reviewed by Gottesman and Shields (13).[2] The figure for incidence in offspring of dual matings (i.e., two schizophrenic parents), symbolized as I(S × S), is from a personal communication with L. Erlenmeyer-Kimling. The percentages for incidence in offspring (IPO) and incidence in siblings(ISS) are consensus figures from Slater's review of the literature (15); the general population incidence (GI) is a weighted average of studies tabulated by Slater. Our estimates are as fol-

[1]The liability scale of Falconer (3) mentioned in the first section is the sum of SQ and a score representing environmental factors. Falconer's risk function is 0 if this combined score is below a threshold value and 100% if it is above the threshold. Nevertheless, the two models give identical predictions.

[2]All of the monozygotic twin concordance figures are probandwise rather than casewise or pairwise; for a good discussion of the different ways of computing twin concordance rates, see Gottesman and Shields (13) and Smith (14).

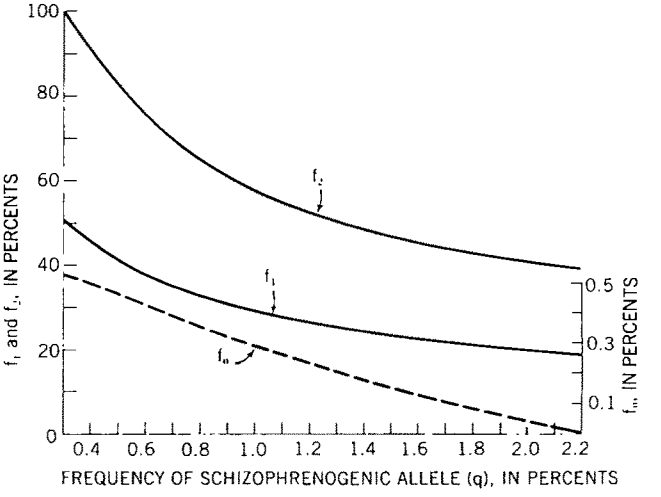
lows: IMZ = 47.0%, I(S × S) = 39.0%, ISS = 8.7%, IPO = 12.0%, and GI = 0.87%. In our calculations, we have averaged ISS and IPO, giving an incidence of 10.4%, because the monogenic and polygenic models both require that the risk for offspring not exceed that for siblings. The observed difference is small.

In both the SML and multifactorial models, any three of the incidences presented above are sufficient to determine the other two. In principle, one might choose any combination of three as data for estimating the parameters of the model. Statistical goodness of fit techniques are not applicable because the standard errors of the data are not known. Since ISS, IPO, and GI are based on by far the largest numbers of cases, they will be used as input data for adjusting the parameters of the models.[3]

ANALYSES: SINGLE MAJOR LOCUS MODEL

When ISS=IPO (i.e., siblings and offspring of schizophrenics are equally at risk), it can be shown that $f_1 = \frac{1}{2}(f_0 + f_2)$.[4] In other words, the risk to the heterozygote lies halfway between the risk to the genetically normal individual and the risk to the homozygote. This case is, strictly speaking, an absence of dominance, but it is often called "intermediate dominance" because the gene is neither fully recessive nor fully dominant. Furthermore, when ISS=IPO, the SML model predicts that the incidence in offspring of dual matings will equal the incidence in identical twins, and both can be computed from the formula,

$$\text{IMZ} = \text{I(S} \times \text{S)} = 2(\text{IPO}) - \text{GI}.$$



Using the incidence estimates presented earlier, the calculated value for IMZ and I(S × S) is 19.9%. This prediction is too low, unless the observed figures for twins and offspring of dual matings have been very much influenced by special environmental effects.

A wide range of possible parameter sets (q, f_0, f_1, f_2) fit the input data (GI = 0.87%, ISS = IPO = 10.4%) (see figure 2). As mentioned above, all of them predict the same IMZ and I(S × S) (19.9%), so this dilemma cannot be escaped by appropriately choosing the parameter set. The population frequency of the pathogenic allele, q, can vary between 0.3% and 2.2%. As q varies, the 3 f values change accordingly. For the lowest permissible gene frequency, the f values are 0.5%, 50.3%, and 100.0% for genetically normal individuals, heterozygotes, and homozygotes, respectively. For the highest permissible gene frequency, the values are

[3]Other treatments of the data are possible (4) and can lead to numerically different results, although the major qualitative conclusions remain unaltered (5). Because of the heterogeneity of the data, it is difficult to decide which approach is better in a statistical sense, although the values used here are believed to be better estimates for family incidences.

[4]Proofs have been omitted here but will appear in a forthcoming article.

FIGURE 2
Risk Functions for the Single Major Locus Model

0.0%, 19.4%, and 38.9%. All these versions of the model fit the data equally well (i.e., they fit the data for GI, IPO, and ISS exactly, and underestimate IMZ to the same extent). For the lowest gene frequency (0.3%), 100% of the homozygotes are predicted to become schizophrenic, but very few schizophrenics are expected to be homozygotes. Most will be heterozygotes or genetically normal. This calculation will be presented in detail because it gives some insight into the workings of the SML model.

According to the Hardy-Weinberg theorem (for an excellent explanation of this theorem, see reference 16), the expected frequencies of each genetic type in the population as a whole are:

genetically normal	$(1 - q)^2 = 99.3\%$
heterozygotes	$2q(1 - q) = 0.7\%$
homozygotes	$q^2 = 0.001\%$

In order to calculate the breakdown into genetic types for schizophrenics, we employ Bayes' theorem, which relates the probability of event B given event A, P(B|A), to the probability of event A given event B, P(A|B):

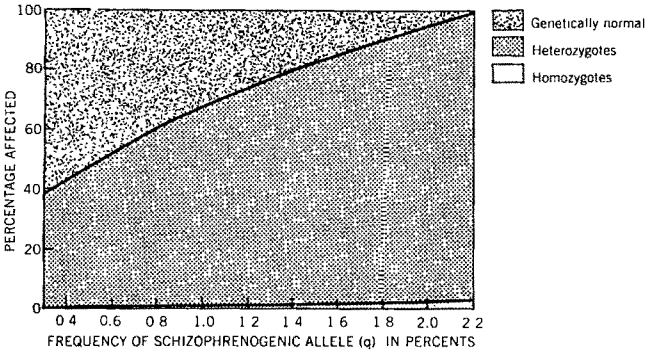
$$\text{P(B|A)} = \text{P(A|B)}\frac{\text{P(B)}}{\text{P(A)}}.$$

The theorem is proved by considering the two equivalent expressions for the joint probability of A and B:

$$\text{P(A)P(B|A)} = \text{P(A and B)} = \text{P(B and A)} = \text{P(B)P(A|B)}.$$

Let A stand for being schizophrenic and B for being homozygous for the pathogenic allele. Then, using Bayes' theorem,

$$P(\text{homozygous}|\text{schizophrenic}) = P(\text{schizophrenic}|\text{homozygous}) \times \frac{P(\text{homozygous})}{P(\text{schizophrenic})}.$$



P(schizophrenic|homozygous) = 100% for this gene frequency; P(homozygous) = .001%, and P(schizophrenic) = .87%. Substituting these values into the equation, P(homozygous|schizophrenic) = 100% × $\frac{0.001}{0.87}$ = 0.1%. Let p_0, p_1, and p_2 stand for the probabilities that a schizophrenic is genetically normal, heterozygous, or homozygous, respectively, for the deleterious allele. We have shown that p_2 = 0.1%, and by similar calculation, p_0 = 61.2% and p_1 = 38.7%. We can summarize the p and f values as follows:

genetically normal	$p_0 = 61.2\%$	$f_0 = 0.5\%$
heterozygous	$p_1 = 38.7\%$	$f_1 = 50.3\%$
homozygous	$p_2 = 0.1\%$	$f_2 = 100.0\%$

Since identical twins are of the same genetic type, it is easily seen that the predicted IMZ = $p_0f_0 + p_1f_1 + p_2f_2$ = 19.9%, which is the figure obtained from the earlier calculation.

In figure 3, the values of p_0, p_1, and p_2 are plotted for each gene frequency. For SML models, the proportion of schizophrenics who are homozygous lies between 0.13% (1 in 769) and 2.24% (1 in 45). The probability that identical twins of homozygous schizophrenics are also affected is given by f_2, which ranges from 100% to 38.9%. These concordance rates are estimates of the degree of genetic determination in individuals in whom genes play their full role, namely, those who are homozygous. We see that, according to some versions of the SML model, genes play an extremely important role when they are present in double dose; but such individuals are very rare, even among schizophrenics. According to other versions of the SML model—which fit the data equally well—the genetic contribution is less striking, even in the homozygote. We can conclude only that the data do not rule out a very high degree of genetic determination in homozygotes.

FIGURE 3
Genetic Composition of the Schizophrenic Population

SAMPLING FOR HOMOZYGOSITY

According to all applicable SML models, homozygous individuals are infrequent, even among schizophrenics (not more than 1 in 45). It is conceivable that these rare individuals are precisely the ones who should be studied biologically. The heterozygote may have an enzyme abnormality that is confined to the brain, whereas in the homozygote it is generalized to peripheral tissues as well. Another possibility is that some abnormal biochemical process is limited to the developmental phase in heterozygotes but persists into adulthood in the homozygote. The usual random sample of patients would be expected to contain mostly heterozygotes and nongenetic schizophrenics (phenocopies). If only homozygotes manifest a particular biological abnormality, one could expect to find at most a few deviant values, but there would be no statistically significant difference between the patient group and controls. For example, in a study of blood levels of the enzyme catechol-*O*-methyltransferase in schizophrenics and controls, no statistically significant difference was found, but the highest values were all among the schizophrenics (17). Other interpretations of this result are, of course, possible, but it suggests the value of sampling procedures that would increase the proportion of homozygotes in the sample.

At first glance, such sampling seems difficult to accomplish. Homozygotes are not necessarily more severely affected than heterozygotes; however, on the chance that they might be, it would be reasonable to work with a severely disturbed group. Certain sampling procedures would be expected to increase the proportion of homozygotes, according to the SML model. One could select schizophrenics with adopted-away offspring who also became schizophrenic. Details of the calculation will not be given here, but with this selection procedure, p_2 (the probability of homozygosity) ranges from 0.63% (for q = 0.3%) to 4.27% (for q = 2.2%). This figure is two to five times greater than that for schizophrenics in general, but it is still too low to be of much use. A more effective method is selecting offspring of dual matings (S × S). The dramatic increase in homozygosity in the sample that would result from this method is evident if one considers diseases like Tay-Sachs or phenylketonuria, where there is a probability of 1 in 4 affected (homozygous) offspring when two phenotypically normal heterozygotes mate.

The probability that offspring of dual matings are homozygous can be easily computed using figure 4. The numbers 0,1,2 refer to the number of pathogenic alleles in each parent; p_0, p_1, and p_2 refer to the probability of each genetic type among schizophrenics, as explained earlier. The probability that offspring of dual matings will be homozygous is calculated by multiplying each entry in the figure (probability of the combination of genetic types, given that both parents are schizophrenic) by the corresponding entry in parentheses (probability offspring are homozygous, given the com-

bination of genetic types). The result is,

$$p_2(S \times S) = \tfrac{1}{4}p_1^2 + p_1p_2 + p_2^2,$$

and it is plotted in figure 5 as a function of gene frequency. The value of $p_2(S \times S)$ ranges from 3.8% to 26.1%, 12 to 29 times the value of p_2 for schizophrenics in general. It is possible to go one step further in the sampling procedure. Since many of the offspring of dual matings are raised in foster homes, it is feasible to select dual-mating offspring who become schizophrenic even though they are raised apart from their parents. Applying Bayes' theorem to this group, we have,

$$P(\text{homozygous}|\text{schizophrenic}) = P(\text{schizophrenic}|\text{homozygous}) \times \frac{P(\text{homozygous})}{P(\text{schizophrenic})}.$$

If we call the probability of homozygosity in adopted-away offspring of dual matings who are schizophrenic $p_2(S \times S, S)$, the formula is,

$$p_2(S \times S, S) = \frac{f_2 p_2(S \times S)}{I(S \times S)}.$$

which is also plotted in figure 5. It ranges between 19.0% and 51.0%, an increase in homozygosity over the general schizophrenic population of from 23 to 146 times.

The expected frequency of homozygosity in adopted dual-mating offspring who are schizophrenic is sufficiently high that statistically significant biologic deviations might be found in this special sample, even if they are manifested only in homozygotes. One caution should be noted: the power of the dual-mating sample selection method will be substantially less if there are several genetic subtypes of schizophrenia. For example, if there are three equally common types, the probability of homozygosity for a particular type will fall by a factor of 9.

Expected Proportion of Homozygotes in Dual Mating Samples

ANALYSES: MULTIFACTORIAL MODEL

In the multifactorial model as we have defined it, there are two unknown parameters that must be adjusted to fit the data: SQ(50% risk) and SQ(99% risk). In order to fit the selected estimates of general incidence (.87%) and incidence in siblings and offspring (10.4%), the SQ values are SQ(50% risk) = 137 and SQ(99% risk) = 148. The analogy with IQ is still more or less applicable, if instead of the risk for schizophrenia we think of the "risk" for graduating from college. An individual with an IQ of 137 would have a 50% probability of graduating; with an IQ of 148, the probability would be 99%. Of course the risk function for college graduation in terms of IQ would have a different shape.[5] The fit of the multifactorial model to the incidence estimates for identical twins and offspring of dual matings is somewhat better than for the SML model, but the errors are in the opposite direction. The predicted IMZ is approximately 61% (actual IMZ = 47%) and the predicted $I(S \times S)$ is approximately 54% (actual = 39%). Since the common environment shared by identical twins and the unfavorable rearing conditions of offspring of dual matings presumably elevate the observed frequencies in those categories, the difference between observed and predicted incidences may be less than our calculations suggest for the SML model and more for the multifactorial model. It is not possible, therefore, to decide between them on the basis of these data.

If an SQ of 148 has a 99% risk, we may ask how frequent those SQs are in the general population. Since SQ has been scaled to be normally distributed with a mean of 100 and a standard deviation of 15, this question can be answered directly by consulting tables of the normal curve: 0.08% of the general population

[5]According to the risk function we have selected, SQ(1%) is 126, so individuals with SQs below 126 are at less than 1% risk for becoming schizophrenic. This includes 96% of the population.

will have an SQ greater than or equal to 148. We can also calculate the proportion of schizophrenics with SQs greater than or equal to 148. To do this, we again apply Bayes' theorem:

$$P(SQ \geq 148 \mid \text{schizophrenic}) = P(\text{schizophrenic} \mid SQ \geq 148) \times \frac{P(SQ \geq 148)}{P(\text{schizophrenic})} =$$

$$\geq 99\% \times \frac{.08}{.87} = 9.1\%.$$

Stated another way, 9.1% of the schizophrenic population (1 out of 11) is predicted to have a genetic vulnerability (SQ) so high that their risk would be 99% or greater were they to start life over again in a new environment. If an individual in this category had an identical twin, the twin's risk would be the same—99% or higher. According to the multifactorial model, therefore, in a substantial proportion of schizophrenics (1 out of 11) the illness is almost completely genetically determined. Sampling methods similar to those described for the SML model can be used to increase the proportion of these individuals in the sample.

CONCLUSIONS

Several conclusions can be drawn from these analyses. First, it seems that neither of these simple models can adequately account for the data. If incidence in the general population and in offspring and siblings of schizophrenics are used as input data, the predicted incidence in identical twins and in offspring of dual matings is too low for the SML model and too high for the multifactorial model. It may be that a model with two interacting genes can account for all five incidences, since the interaction could tend to increase IMZ and I(S × S) relative to the other frequencies.

According to both models, genetic factors may be more important than the observed identical twin concordance rate of 47% might suggest. In the SML model, several sets of parameters (gene frequencies and penetrances) can explain the data equally well—or poorly—and according to some of the acceptable parameter choices, homozygotes are rare but have a very high genetic risk. The multifactorial model predicts that a significant subgroup of the schizophrenic population—1 out of 11—has an extremely high genetic risk, 99% or more.

Finally, it is worth noting that both models predict genetic heterogeneity among schizophrenics. In the SML model, some schizophrenics are homozygous, some are heterozygous, and some are genetically normal. In the multifactorial model, some schizophrenics have a high SQ, and some have a low SQ. Biologic attributes related to the same gene(s) might not, therefore, be found in all schizophrenics. We have suggested some practical ways of increasing the probability of selecting individuals whose illnesses are highly genetically determined, a strategy that might improve the likelihood of discovering biologic differences.

Serum Creatine Phosphokinase in Schizophrenia

BY HERBERT Y. MELTZER, M.D.

The author notes that increased serum creatine phosphokinase (CPK) activity is found in the majority of hospitalized acutely disturbed schizophrenics and patients with affective psychoses. It is probable that some of these increases do not result from nonspecific factors such as activity, trauma, or stress, which do cause increases in some cases. Those patients who show increased CPK activity have more florid psychopathology and tend to have higher CPK levels in nonacute periods than those without increases. First-degree relatives of psychotic patients with elevated serum CPK have high-normal or slightly increased serum CPK. There is also evidence of other neuromuscular dysfunction in psychotic patients. The author concludes that the investigation of CPK may have considerable heuristic value for the study of schizophrenia and other psychoses.

SERUM OR PLASMA and the formed blood elements have proved to be convenient and safe sources of biologic material for investigators studying biochemical aspects of the schizophrenias and affective psychoses. This article will review one such approach to the biology of schizophrenia—the investigation of serum creatine phosphokinase (CPK) activity. I will focus on seven areas: 1) the origin of the serum enzyme, 2) nonspecific causes for increased CPK activity, 3) clinical characteristics of patients with and without increases, 4) serum CPK activity in nonpsychotic periods in psychotic patients with and without increases, 5) serum CPK activity in first-degree relatives of psychotic patients, 6) comparison with serum CPK increases in patients with acute brain diseases, and 7) other evidence of neuromuscular dysfunction in psychoses.

Increased serum CPK activity has been found in some schizophrenic patients experiencing an acute psychotic phase (1–10). Increases are also present in patients with acute affective psychoses (2, 5, 11). In a recent study of 187 acutely psychotic patients—163 with schizophrenia and 24 with affective psychoses—it was found that 47.1% of the patients (N=88) had increased serum CPK activity in samples obtained within 48 hours of admission (5). Serum CPK levels were then determined each weekday throughout hospitalization, and nearly two-thirds of the patients who showed increases at admission also had one or more increases later in hospitalization. Fifty-four patients who had not shown increased CPK activity at admission did so later during their hospitalization. This indicates that serum CPK determinations must be made throughout hospitalization if all patients with increased CPK activity are to be identified. The increases range from just above the 95% upper limit of normal for each race-sex group up to 50 times the upper limit; the median increase is 2 to 3 times the 95% upper limit. The increase lasts 1 to 3 days in half of the cases but is much longer in others (4, 5).

ORIGIN OF SERUM CPK ACTIVITY

There are now 3 known isozymes of CPK: a brain type (BB), a skeletal muscle type (MM), and a cardiac muscle type (MB). Each type is a dimer made up of some combination of B and M subunits. Brain and skeletal muscle have almost exclusively BB and MM type CPK, respectively; cardiac muscle has a mixture of MB, BB, and MM (12, 13). Other organs have only small amounts of CPK and generally do not contribute to any increase in serum CPK activity. The isozymes of CPK can be identified by chromatographic, electrophoretic, or radioimmunologic methods. The CPK in the serum of schizophrenics has been identified as the skeletal muscle type by chromatographic and electrophoretic methods; no brain type was found (3, 4). This suggests that the origin of the CPK is skeletal muscle, a hypothesis that is further supported by findings of increased serum aldolase (2, 3) and pyruvate kinase (according to the unpublished data of Gordon R. Pschedit and myself) in psychotic patients with increased serum CPK activity. Like CPK, elevated aldolase and pyruvate kinase levels in serum are associated with skeletal muscle disease.

There is some controversy as to whether cerebrospinal fluid CPK activity is increased in acute schizophre-

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Meltzer is Professor, Department of Psychiatry, Pritzker School of Medicine, University of Chicago, 950 East 59th St., Chicago, Ill. 60637, and Director of Adult Services, Illinois State Psychiatric Institute.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grants MH-16217 and MH-18396 from the National Institute of Mental Health and by State of Illinois Department of Mental Health grant 431-13-RD. Dr. Meltzer is recipient of U.S. Public Health Service career scientist award MH-47808.

The author wishes to thank Pamela Holy, Glenn Lucht, and Robert Moretti for assistance in research design and data analysis.

nia. No increases were found in several studies (4, 14, 15), but there is one report of increased cerebrospinal fluid CPK levels in acute schizophrenics (16) and another of increases in patients with LSD psychoses (17). Further study of this problem with sensitive methods for determination of CPK activity or protein and careful attention to potential artifacts is needed.

Although the evidence I have reviewed may seem to indicate that the origin of the serum CPK in psychotic patients is skeletal muscle, uncertainty has been introduced by a report that brain type CPK is unstable in serum, especially in vivo, with rapid conversion to the cardiac and skeletal muscle types (18). We (Hyong Won Cho, Jong I. Joung, David J. Goode, and myself) have partially confirmed this in work that showed human brain type CPK to be unstable in vitro; after incubation for 42 hours it migrated like the cardiac type and a species intermediate between cardiac and skeletal muscle type developed. We could not identify any skeletal muscle type even after prolonged incubation in vitro; however, it is possible that a species that migrates like skeletal muscle type CPK could be produced in vivo from brain CPK.

FACTORS NOT RELATED TO PSYCHOSIS AS POSSIBLE CAUSES OF ELEVATED SERUM CPK ACTIVITY IN PSYCHOTIC PATIENTS

Intramuscular injections may elevate serum CPK activity. Although less than 50% of patients given intramuscular chlorpromazine (Thorazine) have increased serum CPK levels following injection (19), all patients who have received such injections should be excluded from studies of serum CPK. In order to avoid the necessity of eliminating the majority of psychotic patients whose serum CPK would be of research interest, intramuscular injections should be avoided. Oral psychotropic medication does not influence serum CPK levels in man, and if parenteral medication is needed, subcutaneous prolixin enanthate or intravenous haloperidol might be used. Alcoholism (20) and muscle trauma may also increase serum CPK activity and must be excluded by history, laboratory, and physical examination. Restraining psychotic patients for purposes of management frequently causes sufficient trauma to produce large increases in CPK activity. Dietary factors, including starvation, have not been found to increase serum CPK activity (21).

Stress does not usually increase serum CPK activity in people without psychotic disorders: nonpsychotic psychiatric patients experiencing severe anxiety, agitation, or depressive symptoms do not have increased serum CPK levels (4, 5, 11), and preoperative patients generally have normal serum CPK activity (22). However, we have found moderate increases in serum CPK levels in some psychotic patients before hospital discharge and in several volunteers before psychotomimetic drug administration that may be related to stress (4, 23).

Physical activity is a well-known cause of increased serum CPK activity (24). However, very strenuous activity (e.g., crew racing or marathon running) is generally required to produce increases, except in a small percentage of so-called enzyme-labile subjects who have large increases in serum CPK activity with relatively slight motor activity (24). A variety of indirect evidence summarized elsewhere (25) suggests that increased motor activity is not a sufficient explanation of the increased serum CPK levels in most psychotic patients. We have recently found that exhausting isometric exercise does not produce increases in serum CPK levels in psychiatric patients that exceed those present during other phases of hospitalization (26). Although Foster and Kupfer (8) reported correlations between serum CPK levels during certain periods of the day and non-dominant-arm motor activity monitored by telemetry, and we have found that nurses' ratings of motor activity and CPK activity are significantly correlated (5), this does not prove causality. In some patients, both motor activity and serum CPK activity could be the consequence of a basic neurochemical abnormality in psychosis, e.g. increased dopaminergic activity. Sleep disturbance in psychotic patients, particularly non-REM sleep time, is negatively correlated with serum CPK levels (27) and may be another example of a central nervous system function that correlates with serum CPK levels without requiring a causal relationship. In normal volunteers, sleep deprivation for 48 hours can produce modest increases in serum CPK activity (28).

CLINICAL CHARACTERISTICS OF PSYCHOTIC PATIENTS WITH AND WITHOUT INCREASED SERUM CPK ACTIVITY

My colleagues (Glenn Lucht and Pamela Holy) and I have studied the clinical characteristics of psychotic patients with and without increased serum CPK activity at admission or at any time during hospitalization to identify the factors that correlate with and perhaps contribute to the increases (5). Such analyses are critical in biologic investigations of this type because of the high likelihood of heterogeneity in the schizophrenic syndrome and because the biologic characteristic under study may be a state-dependent variable rather than a stable trait. This would mean that the clinical state of the patient at the time(s) of study would exert an important influence on the presence of the biochemical abnormality.

I will summarize only our major findings here. The time of onset of psychotic symptoms was significantly related to the presence or absence of increased serum CPK activity. Increased serum CPK activity at admission was significantly more frequent in patients who had had gross psychotic symptoms for less than 1 week (54 of 92 patients, or 58.7%) than in patients who

had had symptoms for more than 1 week (34 of 95 patients, or 35.8%) (χ^2=8.945, p<.005). This is undoubtedly because serum CPK levels are only transiently increased. General characteristics of schizophrenic patients (e.g., acute or chronic, paranoid or nonparanoid) were not related to increases except that chronic nonparanoid schizophrenic patients had significantly fewer increases at admission (3 of 15 patients) than the other three groups (76 of 148 patients) (χ^2=4.178, p<.05). Schizophrenic patients with and without increased serum CPK at admission did not differ on Stephens-Astrup prognosis criteria.

We also found that psychotic patients with increased serum CPK at admission had higher peak ratings on 5 of 8 nonredundant items of a 14-item daily behavior rating scale (derived from Hargreaves [29]) administered during the first week of hospitalization than psychotic patients without CPK increases. The significantly different items included ratings of psychotic behavior, paranoia, lack of effective contact with staff and patients, hyperactivity, and anger. There were no significant differences in ratings of depression, underactivity, and anxiety. A discriminant function analysis of all 14 items of the scale indicated that peak admission ratings significantly discriminated between patients with and without increased serum CPK activity (according to the unpublished data of Glenn Lucht, Pamela Holy, and myself). Psychotic patients with increased serum CPK levels had higher ratings on the psychiatric illness (a measure of global psychopathology) and anxious manner items. Both analyses statistically controlled for differences in the time of onset of psychotic symptoms between the two groups.

Similar analyses using mean behavior ratings throughout hospitalization to compare patients who had increased serum CPK activity at any time during hospitalization with those who had no increases revealed that the former group had significantly greater psychotic behavior ratings (5). A discriminant function analysis of the 14-item scale showed that the best discriminants were the psychiatric illness item for patients with increases and the paranoia item for those without increases (according to the unpublished data of Glenn Lucht, Pamela Holy, and myself). These analyses also controlled for differences in the time of onset.

In addition to these differences in psychopathology, schizophrenic patients with increased serum CPK levels at any time received higher doses of phenothiazine and had significantly longer hospitalizations than those who had no increases (5). The greater length of hospitalization was exclusively due to the patients who had late increases in serum CPK activity, suggesting that a late increase could be some indication of exacerbation of the psychosis. We are currently exploring this possibility.

It appears that those patients with increased serum CPK activity at admission or later in hospitalization tend to have a more florid psychosis that is more resistant to treatment during that episode. The psychotic patients without serum CPK increases tend to be acutely ill patients with brief, treatment-responsive illnesses or chronic patients who are admitted after only relatively slight intensification of their psychoses.

SERUM CPK ACTIVITY IN NONPSYCHOTIC PERIODS AS A FACTOR IN SERUM CPK ELEVATIONS

I assessed the mean serum CPK levels for each patient, based on all samples throughout hospitalization, excluding those which exceeded the 95% upper limit of normal and those taken 5 days or less after a muscle biopsy or 3 days after an intramuscular injection (5). The mean serum CPK levels in psychotic patients with increased serum CPK levels at any time were significantly greater than in psychotic patients who never had an increase. Similar results were obtained using predischarge serum CPK levels without any exclusions, which suggests a biochemical diathesis toward increased serum CPK levels in those patients who have increased serum CPK activity when psychotic. These results also suggest that such individuals may have increased permeability of skeletal muscle (or brain) or slower inactivation or clearance of CPK from serum.

SERUM CPK LEVELS IN FIRST-DEGREE RELATIVES OF PSYCHOTIC PATIENTS

Moline and I (4, 5, 11) have previously reported that first-degree relatives of both schizophrenic patients and patients with affective psychoses have serum CPK levels that are near to or slightly exceed the 95% upper limit of normal. To date, we have obtained one or more serum CPK samples from 314 first-degree relatives of 134 psychotic patients: 32.2% (N=101) have had at least one elevation of serum CPK levels based on the 95% norm for their respective race-sex groups (5). The percentages of increases were approximately the same in parents, siblings, and children of these psychotic patients. The incidence of increased serum CPK activity in 253 first-degree relatives of patients who themselves had increased serum CPK activity (37.2%, N=94) was significantly greater than the incidence in 61 first-degree relatives of patients who did not have serum CPK elevations (11.5%, N=7) (χ^2=13.699, p<.001). The serum CPK levels from families as a unit have also been considered; it was determined that 54.4% (N=56) of the 103 families of patients with an increase had at least one family member with increased serum CPK, while the figure was only 16.1% (N=5) for 31 families of patients without an increase (χ^2=12.551, p<.001) (according to the unpublished data of Robert Moretti and myself). This finding is of interest because it suggests that there could be a genetically determined predisposition toward increased serum CPK levels. Our findings in first-degree relatives take on added significance in that

we have found that serum CPK levels are under significant genetic control in both normal and schizophrenic monozygotic twins, with heritability indices of 0.6–0.8 (30, 31).

SERUM CPK ACTIVITY IN ACUTE BRAIN DISEASES

Increased serum CPK activity has been reported in patients with hemorrhagic and thrombotic cerebrovascular disease, necrotic gliomas, cerebral anoxia, status epilepticus, brain trauma (e.g., gunshot wounds), subarachnoid hemorrhages, drug-induced coma, encephalitis, and meningitis (32, 33). Other characteristics of the serum CPK increases in acute brain syndromes and acute psychoses are similar and differ distinctly from those in chronic neurogenic muscle disease or a myopathy such as polymyositis (5). These characteristics include 1) time from onset of symptoms to the first rise in serum CPK activity, 2) time from the onset of the CPK increase to the peak increase in CPK activity, 3) duration of increased CPK activity, 4) magnitude of increased serum CPK activity, and 5) percentage of patients who have increased serum CPK activity.

Although there are basic similarities in the time course and magnitude of the serum CPK increases in psychotic patients and patients with well-defined acute brain diseases, this does not mean that these increases have the same etiology. It is possible that disruption of tonic upper motor neuron influences on lower motor neurons, loss of trophic substances transported to muscle via blood or nerve, elaboration of myotoxic substances by the brain itself, changes in muscle blood flow, muscle electrolyte composition, oxygen supply, or muscle contraction patterns and intensity might occur in the acute psychoses and acute brain syndromes and have an effect on muscle enzyme efflux.

Other possible causes of enzyme release might also come into play during an acute psychosis or an acute organic brain disease. Entirely different factors or variations of a similar process might account for the increased muscle enzyme release in this wide range of disorders. For example, abnormalities of catecholamines and indoleamines are being investigated in the schizophrenic psychoses (34, 35), affective psychoses (36, 37), acute cerebrovascular diseases (38), and Duchenne-type muscular dystrophy (39). Serotonin can increase serum CPK levels in rats (40) and produce skeletal muscle pathology under various conditions (41, 42). I have observed that the hallucinogenic indole harmaline can increase serum CPK levels in rabbits. Brain lesions in cats can increase some serum enzymes (43).

It should be apparent from this brief discussion that 1) there are mechanisms by which central processes might influence muscle enzyme release; 2) serum CPK increases in the schizophrenic and affective psychoses indicate at least one shared pathophysiologic process (increased muscle enzyme efflux) but not necessarily a common etiology of that process; and 3) the acute psychotic states share this pathophysiologic process with acute organic brain diseases.

SERUM CPK ACTIVITY AND NEUROMUSCULAR DYSFUNCTION IN SCHIZOPHRENIA

On the basis of the evidence of a link between psychosis and the excessive release of CPK from skeletal muscle, we initiated a study of the skeletal muscle fiber morphology in first-degree relatives, psychotic patients, and normal volunteers. Briefly, we found that many psychotic patients had muscle fiber abnormalities, usually confined to a small number of fibers, which is more consistent with a denervation process than a myopathy (44–46), although the distinction between these two classes of muscle disease is blurred (47). Less frequent but similar changes were found in the biopsies of first-degree relatives of psychotic patients (46). These findings led to an examination of the subterminal motor nerves of psychotic patients. We found that 30 of 68 psychotic patients (44%) and 5 of 8 of their first-degree relatives (68%) had excessive branching of subterminal motor nerves and excessive multiple innervation of muscle fibers (46, 48, 49). There were also large numbers of sprouts (branches of subterminal motor nerves) without terminal arborizations, and the nerve endings themselves tended to be more fragmented and dispersed than those of the controls (according to the unpublished data of John W. Crayton and myself).

A significant association between elevated serum CPK levels and the presence of an abnormal muscle biopsy has not been shown. The incidence of abnormal muscle biopsies in psychotic patients with and without increased serum CPK levels was not significantly different, and 90% of the 187 patients had either increased serum CPK activity or an abnormal biopsy (46).

Preliminary neurophysiologic investigations have also been carried out by Crayton and associates (50), who studied serum CPK activity, skeletal muscle fiber pathology, and subterminal motor nerve branching in 50 psychotic patients. The Hoffman (H) reflex recovery curve, which provides an index of α-motor nerve excitability, was significantly related to the diagnosis of psychosis and serum CPK activity. The H reflex is a monosynaptic response evoked by submaximal stimulation of a mixed motor and sensory nerve (51). The afferent discharge travels in the lower threshold sensory fibers. The H response, recorded from the appropriate muscle, occurs as a result of discharge of the afferent fibers of the two-neuron arc or monosynapse in the spinal cord. When two test stimuli are applied to the mixed nerve at various intervals, the second H response is modified by residual effects of the first stimulus on the α-motor neuron. The ratio of the evoked muscle response following the second stimulus to the response following the first stimulus (H_2/H_1) can be

plotted against the delay between stimuli to generate an H reflex recovery curve. Twenty-one of 35 schizophrenic patients (60%) and 4 of 9 patients with affective psychoses (44%) had abnormal recovery curves, compared with 2 of 20 normal subjects in a control group (10%). The abnormalities were of two types: 1) delayed onset of initial recovery and a markedly reduced or absent peak of secondary facilitation when the second stimulus was given 100–300 milliseconds after the first; and 2) an accentuation of the trough following secondary facilitation at 300–500 milliseconds. Both findings suggest decreased excitability of the α-motor neuron. Each of 9 patients with serum CPK levels that exceeded 300 IU/liter had abnormal recovery curves. It is of interest that increased central nervous system dopaminergic activity can produce decreased α-motor neuron excitability (52), and increased brain dopaminergic activity has been proposed as a factor in both schizophrenia and mania (34, 37). This is but one of the many possible bridges between neuromuscular dysfunction and aminergic theories of the major psychoses.

CONCLUSIONS

Measurement of serum CPK activity in psychiatric patients may have some value for the differential diagnosis of psychotic from nonpsychotic psychiatric patients. However, there are several reasons why such determinations may have primarily heuristic rather than clinical value: 1) the brief duration of any increases, 2) those with less florid symptomatology have increases significantly less frequently than the more severely ill psychotic, and 3) some nonpsychotic as well as psychotic patients may have increases for reasons such as injections, trauma, or alcoholism. Interest in CPK has already led to studies that have demonstrated a variety of pathologic changes in the neuromuscular system of psychotics, including morphologic changes in muscle fibers and subterminal motor nerves (44–46) and physiologic abnormalities in nerve conduction velocity (according to the unpublished data of David J. Goode and myself) and spinal cord reflex mechanisms (50). Other techniques for investigating the spinal cord, motor nerves, and muscle fibers will certainly be employed in the study of psychotic patients and may yield further information about the extent of involvement of the neuromuscular apparatus in psychosis. These studies will contribute to the evidence for an organic component of the major psychoses; they may also provide significant insight into the causes of the major psychoses. It seems unreasonable to think that the causes of the neuromuscular dysfunction will be found to be unrelated to the causes of the psychoses themselves. It is conceivable that determining the causes of the neuromuscular dysfunction can be useful in testing current theories of the etiology of the schizophrenic and affective psychoses or generating new hypotheses.

The Dopamine Hypothesis of Schizophrenia: Focus on the Dopamine Receptor

BY SOLOMON H. SNYDER, M.D.

Alleviation of schizophrenic symptoms by phenothiazines and butyrophenones is associated with blockade of dopamine receptors, while exacerbation of symptoms by amphetamines appears to result from enhanced synaptic activity of dopamine and/or norepinephrine. The author suggests that biochemical labeling of the dopamine receptor with ^{3}H-dopamine and ^{3}H-haloperidol may clarify mechanisms of drug effects on the dopamine receptor.

THE DOPAMINE HYPOTHESIS of schizophrenia is by definition supported by no direct evidence. No one has found anything conclusively abnormal about dopa-

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Snyder is Professor, Department of Pharmacology and Experimental Therapeutics, and Professor, Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, 725 North Wolfe St., Baltimore, Md. 21205.

mine (DA) in body fluids or brains of schizophrenics, but the indirect evidence is impressive. The symptoms of schizophrenia can be selectively exacerbated or relieved by the use of drugs. When pharmacologists decipher the neurochemical mechanisms of these drugs, all evidence points to DA.

DOPAMINE

In most areas of the brain, DA, one of the two principal catecholamines in the brain, is merely the precursor of norepinephrine (NE). It is transformed into NE by the enzyme dopamine hydroxylase; however, some parts of the brain lack dopamine hydroxylase, and DA is the presumed neurotransmitter (1–3) in these areas.

The best known DA neuronal pathway has cell bodies in the substantia nigra of the brain stem with nerve terminals in the corpus striatum, the caudate nucleus, and the putamen. This pathway degenerates in patients with idiopathic Parkinson's disease. The resultant DA depletion is causally related to the symptoms of the disease because replacing the missing DA by treatment with its amino acid precursor L-dopa dramatically alleviates symptoms. Thus in Parkinson's disease a dopamine hypothesis of causation has been translated into proof. A DA pathway important to endocrinology has cell bodies in the arcuate nucleus of the hypothalamus and nerve terminals synapsing on the portal vessels in the median eminence that convey releasing factors from the hypothalamus to the pituitary gland. DA in these neurons regulates releasing factor activity and subsequent endocrine effects.

Other DA pathways may be more related to the symptoms of schizophrenia. Pathways with cell bodies close to the substantia nigra project to the nucleus accumbens and olfactory tubercle, both components of the limbic system of the brain that regulates emotional behavior. Recently described DA pathways with cell bodies in the same areas project to parts of the frontal, cingulate, and entorhinal cerebral cortex, phylogenetically older parts of the cerebral cortex functionally related to the limbic system.

AMPHETAMINE ACTIONS

One way to link a drug to a particular illness is to show that the drug reproduces symptoms of the disease. LSD psychosis was once thought to be a "model schizophrenia"; however, one cannot accurately equate the effects of such psychedelic drugs as LSD with schizophrenic symptoms. Psychedelic drugs produce perceptual changes in the visual sphere, whereas schizophrenic hallucinations are usually auditory. Under the influence of psychedelic drugs, people do not demonstrate classic schizophrenic disorders in affect or thought. Moreover, clinicians rarely mistakenly diagnose individuals under the influence of psychedelic drugs as schizophrenics. By contrast, there are numerous reports of amphetamine psychosis being misdiagnosed as acute paranoid schizophrenia before the history of drug ingestion is obtained. Some psychiatrists studying individuals with amphetamine psychoses have felt that they manifested schizophrenic disorders of affect and thought (4, 5), but others disagree (6). Although the specifics of amphetamine psychoses may not exactly match those of schizophrenia, the mere fact that experienced psychiatrists can mistake the two diagnoses indicates that amphetamine psychosis is probably the best current drug model of schizophrenia.

Amphetamine psychosis is not simply a precipitation of a latent schizophrenia or a sleep deprivation psychosis, since psychosis has been elicited by amphetamine in individuals screened for the absence of any history of schizoid disorders; in some cases the psychosis has occurred within 24 hours (6).

Like amphetamine, cocaine is a widely abused CNS stimulant that can, in high doses, provoke a psychosis that is clinically indistinguishable from acute paranoid schizophrenia. Indeed, most of the symptoms of cocaine psychosis are essentially identical to those of amphetamine psychosis. How does cocaine act? An abundance of pharmacologic evidence indicates that cocaine's behavioral effects result from its facilitation of catecholamine synaptic activities by blocking the reuptake inactivation of catecholamines.

Very large doses (100–500 mg) of amphetamine are required to elicit amphetamine psychosis, but amounts prescribed therapeutically for dieting or stimulant effects rapidly and reproducibly exacerbate schizophrenic symptoms (7). Amphetamine and related drugs such as methylphenidate (Ritalin) do not superimpose a drug psychosis on the schizophrenia but instead worsen the patient's own symptoms. This effect is selective—it is not elicited in depressed or manic patients. There is no other drug known that so specifically and dramatically exacerbates schizophrenic symptoms.

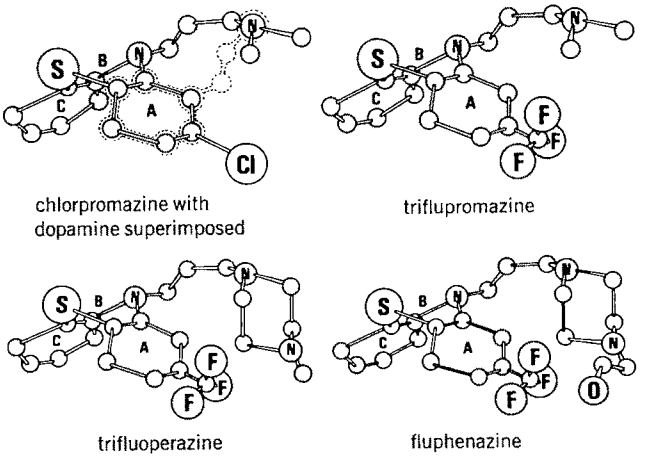
How do amphetamines act? Behavioral effects of amphetamines are exerted via the catecholamines NE or DA. Amphetamines enhance the actions of catecholamines by directly releasing them into the synaptic cleft or by preventing their inactivation via reuptake into the nerve terminal that released them. Amphetamines do not affect other neurotransmitter or biochemical systems in the brain so specifically and potently. Although it is difficult to make a clear-cut distinction, the actions of amphetamines in exacerbating schizophrenic symptoms and eliciting amphetamine psychosis probably involve brain DA more than NE. While the neurochemical effects of amphetamines and cocaine are similar, there are differences; cocaine apparently lacks the amphetamines' capacity to directly release catecholamines.

If amphetamines exacerbate schizophrenic symptoms by increasing synaptic DA, then other pharmacologic maneuvers that produce the same biochemical

end product should also worsen schizophrenic symptoms. The simplest technique to determine this would be the administration of L-dopa, the precursor of DA. In the few studies in which L-dopa has been administered to schizophrenics, it worsened behavioral abnormalities in much the same way that amphetamines do (8, 9).

PHENOTHIAZINES

Clinical psychopharmacologists generally agree that phenothiazines exert a specific antischizophrenic action and act primarily on the fundamental symptoms of schizophrenia (10). Their effects are not merely sedative, since they activate withdrawn patients and calm hyperactive individuals. Many other psychotropic drugs, including potent sedatives and antianxiety agents, have failed to provide selective benefits in schizophrenia comparable to the impressive actions of phenothiazines and related agents. Moreover, while phenothiazines are used in the treatment of mania and many other conditions, the relief they afford in schizophrenia appears to be far more specific than their effects in other emotional disturbances.



Understanding the mechanisms of action of phenothiazines might shed light on brain mechanisms in schizophrenia. Unlike the amphetamines, the phenothiazines do not possess obvious chemical resemblance to particular neurotransmitters (figure 1). However, these drugs probably act by blocking postsynaptic receptor sites for the neurotransmitter actions of DA. This theory was first advanced by Carlsson (12) on the basis of limited indirect biochemical data. Carlsson hypothesized that if phenothiazines block DA receptors, animal behavior which resembled that induced by the DA depletion after treatment with such drugs as reserpine would result. Postsynaptic neurons would respond to the receptor blockade by sounding an alarm calling for more dopamine. By a feedback system DA cells would then fire more frequently and release more DA, providing an excess of DA metabolites or breakdown products. Carlsson observed an increase in DA metabolites after phenothiazine administration and showed that these biochemical effects of phenothiazines were correlated with the clinical potency of the drugs. This is a crucial task in relating drug "effect" to "mechanism of clinical action."

Since phenothiazines are highly reactive chemicals, they produce many biochemical actions, most of which do not correlate with clinical effects. Thus the phenothiazine promethazine (Phenergan) is a potent antihistamine, but it is totally ineffective in treating schizophrenia, although it exerts most phenothiazine-induced biochemical actions just as effectively as chlorpromazine. Carlsson showed that the increase in DA metabolites produced by chlorpromazine and other phenothiazines was in proportion to their milligram potency in treating schizophrenia, but promethazine was totally ineffective.

Subsequently, other pharmacologists found that the increased formation of DA metabolites elicited by phenothiazines derives from an increased synthesis and, presumably, release of DA (13, 14). Only recently did Aghajanian and Bunney (15) actually show that the DA neurons fire more frequently after phenothiazine administration and that phenothiazines actually block the neurophysiologic effects produced by the injection of minute amounts of DA onto postsynaptic cells possessing DA receptors. Thus, at a neurophysiologic level, one can now demonstrate the synaptic actions of DA, which appears to function as an inhibitory neurotransmitter, and the capacity of phenothiazines to block these effects in proportion to their clinical efficacy.

Because neurophysiologic studies are quite difficult to perform, only a limited number of drugs can be screened. It has been possible to monitor DA receptor activity biochemically via two techniques—an indirect and a more recent direct approach. Cyclic adenosine monophosphate (cAMP) is thought to be a second messenger mediating the actions of many hormones and neurotransmitters. Kebabian and associates (16) showed that a cAMP accumulating system, or adenylate cyclase, in areas of the brain rich in DA nerve terminals responds selectively to DA and is affected much less by other catecholamines (table 1). This DA-sensitive adenylate cyclase is thus linked in some way to the DA receptor and provides an indirect reflection of dopamine receptor activity that can be readily monitored in vitro. As seen in table 1, phenothiazines inhibit the effects of DA on the adenylate cyclase in proportion to their clinical potency (18, 20). Thus trifluoperazine (Stelazine) and fluphenazine (Prolixin, Permitil), two very potent phenothiazines in clinical practice, are considerably more active on the DA-sensitive adenylate cyclase than chlorpromazine, which is clinically less potent.

FIGURE 1
Phenothiazines With the Side Chain "Tilted" Toward the A Ring*

*From Feinberg and Snyder (11).

In order to directly measure the DA receptor biochemically, we labeled neurotransmitter receptors in the brain by binding radioactive forms of the neurotransmitter or its antagonists to synaptic membranes in brain homogenates (21–23). Using such procedures, we recently succeeded in biochemically identifying the DA receptor in the brain (17). DA receptor binding displays all the characteristics one would expect of the DA receptor. Of the various catecholamines, DA has by far the greatest affinity—it is almost 20 times more potent than NE and several thousand times more potent than isopoterenol, the catecholamine with greatest affinity for β-adrenergic receptors. The relative potencies of phenothiazines competing for DA receptor binding closely parallels their clinical potency and their effects upon the DA-sensitive adenylate cyclase. Optical and geometrical isomers of phenothiazine-related drugs are uniquely valuable in the study of receptor specificity. If the physical properties of the two isomers, especially the optical isomers, are essentially the same, any difference in pharmacologic potency must be related to the structure of the receptor sites. The isomeric specificity of the DA receptor binding sites for the isomers of butaclamol and flupenthixol parallels the influences of these isomers on the DA-sensitive adenylate cyclase and their pharmacologic potency in intact animals (table 1).

Interestingly, one group of drugs does not fit in particularly well in either the DA-sensitive adenylate cyclase or DA receptor binding. Butyrophenones such as haloperidol (Haldol) are considerably more potent on a milligram basis than phenothiazines in vivo but are not particularly potent in their influences on the DA receptor in vitro. However, in pharmacologic paradigms in intact animals the potencies of butyrophenones in apparently blocking DA receptors correlates well with their clinical actions. The discrepant actions of butyrophenones on dopamine receptors have been resolved by labeling the receptor with ^{3}H-haloperidol (24–26). Haloperidol and dopamine appear to bind to discrete antagonist and agonist states of the receptor. The clinical potencies of butyrophenones and phenothiazines are predicted impressively by their affinities for haloperidol binding sites (24).

How might phenothiazines be physically accommodated by the DA receptor? In what appears to be their optimum shape or conformation, the side chain of phenothiazines tilts toward the A ring rather than being extended symmetrically between the A and C rings (figure 1). Since the A and C rings are essentially identical except for the presence of a substituent at the 2-position on the A ring, it is likely that this substituent directs the side chain toward the A ring. In the conformation with the side chain approximating the A ring, the amino nitrogen of the side chain and the A ring correspond impressively to the amine and benzene rings of DA and indeed can be superimposed (figure 1) (11, 27, 28). One might predict that chemical factors stabilizing this DA-like conformation of phenothiazines would facilitate DA receptor blockade and enhance clinical potency. The most obvious chemical feature of importance for this conformation is the presence of the substituent at the 2-position on the A ring. A phenothiazine drug lacking such a substituent would possess symmetrical A and C rings so that the side chain would be fully extended in the midline and would not well approximate the DA conformation. In accordance with this prediction, of all the widely used phenothiazines in clinical practice, the only two which are systematically inferior are promazine (Sparine) and mepazine (Dartal) (10). The sole systematic chemical difference between these two drugs and the other phenothiazines is the absence of a substituent on the A ring.

What determines which of the phenothiazines that are clinically efficacious will be the most potent on a milligram basis? One might presume a priori that differences in metabolism and ability to penetrate into the brain account for such large differences in potency that 5 mg of fluphenazine are as potent as 400 mg of chlorpromazine. However, pharmacodynamic studies indicate that such factors cannot account for the differences in clinical potency. Moreover, when assayed directly against DA receptors in binding studies or with the DA-sensitive adenylate cyclase, differences in clinical potency are predicted by affinity for the DA receptor. One might therefore conclude that the more potent phenothiazines must be capable of assuming the DA-like conformation more frequently than less potent phenothiazines. If the A ring substituent and the amine side chain are mutually attracted by chemical forces, the chemical variations that increase these attractive

TABLE 1
Phenothiazine and Thioxanthene Drug Effects on Specific Dopamine Receptor Binding and a Dopamine-Sensitive Adenylate Cyclase

Drug*	Relative Potency in Competing for Dopamine Receptor Binding**	Relative Potency in Inhibiting Dopamine-Sensitive Adenylate Cyclase of Rat Corpus Striatum***
Haloperidol	50	50
(+)-Butaclamol	1200	728
α-Flupenthixol	625	4545
Fluphenazine	465	1087
Trifluoperazine	181	250
Triflupromazine	214	—
Perphenazine	125	—
Chlorpromazine	100	100
Promazine	27	17
(−)-Butaclamol	8	<1

*Drugs are listed in approximate descending order of milligram potency in treating schizophrenia and eliciting extrapyramidal side effects.

**Potency in competing for binding to the dopamine receptor is defined as the reciprocal of the nanomolar concentration to occupy 50% of receptor binding sites × 1.5 × 10^5 in calf striatal membranes using the assay of Burt and associates (17). Thus (+)-butaclamol inhibits binding 50% at 1.25 × 10^{-7} M concentration. Larger values indicate greater potency.

***Data are derived from the studies of Miller and associates (18) and Lippman and associates (19). Clement-Cormier and associates (20) obtained similar results.

forces should stabilize the DA conformation of phenothiazines, producing more potent drugs. Phenothiazines with a triflumethyl substituent in the A ring are more potent than those with a chlorine substituent. Molecular modeling (figure 1) and computer calculations (11) indicate that the triflumethyl group approaches more closely to the amine side chain, providing for greater attractive forces than a chlorine substituent; therefore, drugs with triflumethyl groups should be more potent in binding to the DA receptor. Similarly, phenothiazines with simple piperazine side chains, such as trifluoperazine (Stelazine), are more potent clinically than those with alkylamino side chains. Again simple observations of space-filling molecular models indicate how the piperazine side chain affords more points of attraction to the A ring substituent than the alkylamino side chain. Drugs with hydroxyethylpiperazine side chains, such as fluphenazine (Prolixin), are systematically more potent than those with simple piperazine rings, such as trifluoperazine. Again, drugs with hydroxyethylpiperazine groups provide still more attractive possibilities than piperazine. Thus, simply by designing phenothiazine drugs that more accurately mimic the DA conformation, one can obtain progressively more potent agents.

Phenothiazines may exert presynaptic effects on DA neurons as well, since Seeman and Lee (29) have recently shown that they inhibit DA release in proportion to their clinical potency. The correlation with actual milligram potency is better for this effect than for postsynaptic receptor blockade.

CONCLUSIONS

The blockade of DA receptors correlates with the antischizophrenic activity of phenothiazines, and more potent agents seem almost sculpted to plug into the DA receptor, although they were synthesized by chemists who never heard of DA. The case for the hypothesis that phenothiazines exert their clinical actions by blocking DA receptors is rather impressive. While blocking DA receptors relieves schizophrenic symptoms, amphetamines, which flood the receptors with more DA, exacerbate schizophrenic symptoms. However, none of this proves that DA is the causative "germ" of schizophrenia. The biologic abnormality in a major portion of the schizophrenic population implied by compelling genetic evidence could be far removed from DA. No one has yet shown a specific aberration in DA in the brains of schizophrenics, but Wise and Stein (30) found that dopamine hydroxylase activity is lower in the brains of schizophrenics than in control subjects. A deficiency of this enzyme would result in a build-up of DA, consistent with the effects of drugs on schizophrenic behavior. In one study attempting to confirm the abnormality of dopamine hydroxylase in the brains of deceased schizophrenics, some low dopamine hydroxylase levels were found, but these seemed to depend on how long the brain had been stored after death before assay (31).

Arguments derived from drug influences on schizophrenic behavior are flawed. Phenothiazines do not "cure" all schizophrenics. Many schizophrenics in remission after phenothiazine treatment still have aberrant behavioral patterns. Of course, it can be argued that one can hardly expect a drug, even one that acts at the specific locus of abnormality in the brain, to completely reverse events that have been going on for a lifetime. Certainly, while appropriate antibiotics arrest advanced cases of tuberculosis, the patient is still left with sequelae of the disease. Such analyses are complicated by the likelihood that schizophrenia represents a conglomerate of several "diseases."

The use of amphetamine psychosis as a model for schizophrenia has been questioned on the grounds that the former disorder is usually paranoid, rarely resembling other forms of schizophrenia, and does not display abnormalities of thought and affect that are classic for schizophrenia. Some investigators have observed thought and affect disorders in individuals with amphetamine psychosis. It may be difficult to pick up thought and affect abnormalities in intelligent patients with well-organized paranoid systems of ideation. Also, even if amphetamines cause changes in the brain similar to those which occur in true schizophrenics, major differences are apparent since the drug psychosis occurs in a nonschizophrenic individual who knows that the episode is likely to be short-lived. By contrast, a schizophrenic has experienced an abnormal mental state for most of his life and has no hopes of any major relief. The selective exacerbation of schizophrenic symptoms by low doses of amphetamines is probably stronger evidence for the psychotogenic capabilities of these drugs.

Despite these reservations, there is little doubt that research prompted by the relationship of drugs, DA, and schizophrenia has greatly advanced our understanding of psychotropic drug action. It is hoped that such research will be relevant to schizophrenia.

The Psychedelic Model of Schizophrenia: The Case of *N,N*-Dimethyltryptamine

BY J. CHRISTIAN GILLIN, M.D., JONATHAN KAPLAN, M.D., RICHARD STILLMAN, M.D., AND RICHARD JED WYATT, M.D.

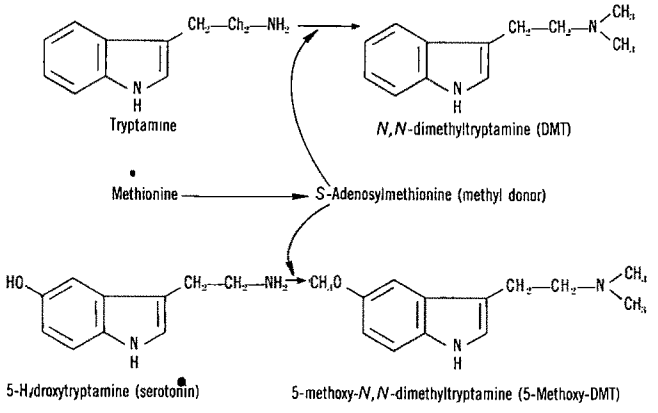
The authors review the research on N,N-*dimethyltryptamine (DMT) as a possible "schizotoxin." DMT produces psychedelic effects when administered to normal subjects, the means are present to synthesize it in man, it has occasionally been found in man, and tolerance to its behavioral effects is incomplete. However, DMT concentrations have not been proven to differ significantly in schizophrenics and normal controls. Also, in vivo synthesis of DMT has not been convincingly demonstrated, and the psychological changes it produces do not closely mimic the symptoms of schizophrenia. The authors conclude that more data are necessary before the validity of this theory can be determined.*

MANY THEORIES of schizophrenia are based on the assumption that the illness is caused by a chemical substance, a "schizotoxin," that would mimic the clinical symptomatology of schizophrenia if it were isolated and administered to normal individuals. An example of this research strategy is the transmethylation hypothesis, first proposed by Osmond and Smythies in 1952 (1). These researchers noted the similarity in chemical structure of mescaline and norepinephrine, an observation that spurred the search for psychedelic methylated metabolites of endogenous compounds in schizophrenic patients that might account for hallucinations, delusions, and other clinical symptoms.

Interest in the transmethylation hypothesis was further stimulated by the work of Pollin and associates (2), who reported in 1960 that methionine, a natural methyl donor, administered in combination with a monoamine oxidase (MAO) inhibitor, exacerbated clinical symptoms in 3 of 9 schizophrenic subjects. Since that time, methionine has been administered to schizophrenics in 10 studies reviewed by Cohen and associates (3). One-third of the patients in these studies exhibited increased clinical symptoms without evidence of organic brain dysfunction. These results suggest that methionine increases the synthesis of an abnormally methylated substance, as yet unidentified, that was responsible for the observed clinical exacerbation.

Several substances have been proposed as candidates for the schizotoxin, including 3,4-dimethoxyphenylethylamine (pink spot), bufotenine, 5-methoxy-*N,N*-dimethyltryptamine, and *N,N*-dimethyltryptamine (DMT) (see figure 1). The first two substances have not been shown to produce psychotic psychological changes when administered to normal individuals (4, 5); in the case of bufotenine, this may be because it does not cross the blood-brain barrier. Little is known about 5-methoxy-DMT, although it has been reported to produce psychedelic effects in normal individuals (6), and urinary concentrations of 5-methoxy-DMT have been noted to increase with clinical exacerbation in schizophrenic patients (7). Figure 1 presents the postulated routes of synthesis of DMT and 5-methoxy-DMT.

In this paper, we shall review current evidence on the role of DMT as a causative agent in schizophrenia. Fortunately there are criteria (modeled after Koch's postulation) with which to evaluate a hypothesized schizotoxin. The following criteria were initially proposed by Hollister (8) and have been slightly modified here:



1. The substance must mimic important clinical aspects of schizophrenia.
2. The substance must be found in man.
3. The precursor must be found in man.
4. The agent must be synthesized in man. (It remains a logical possibility that it is of dietary origin.)
5. The agent must be differentially synthesized or metabolized in schizophrenia.
6. Tolerance to the agent should not develop. (This assumes that schizophrenia is not caused by a substance that is present only briefly and sets irreversible changes in progress.)
7. Neuroleptic drugs must be capable of inhibiting the synthesis, increasing the metabolism, or antagonizing the behavioral effects of the agent.

The body of our paper will consist of an examination of each of these criteria as they apply to DMT.

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

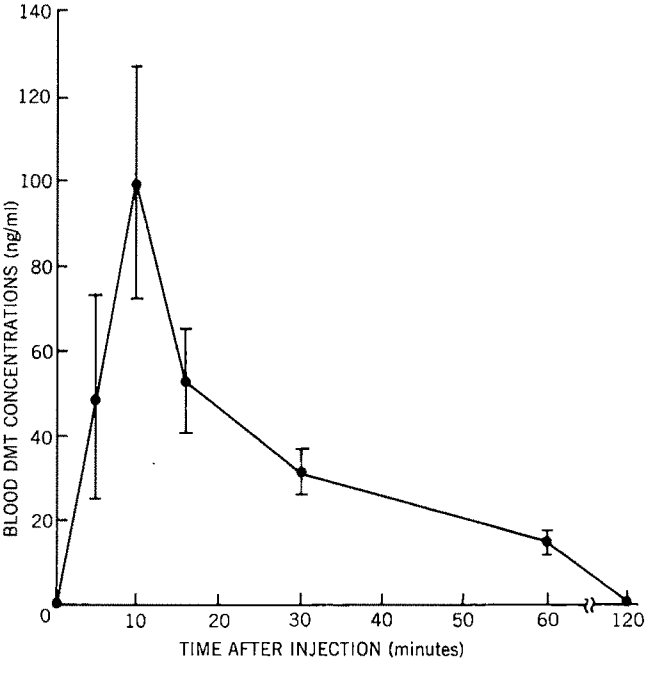
Drs. Gillin and Stillman are Research Psychiatrists, and Dr. Wyatt is Acting Chief, Laboratory of Clinical Psychopharmacology, National Institute of Mental Health, St. Elizabeths Hospital, Washington, D.C. 20032. Dr. Kaplan is Staff Psychiatrist, Menlo Park Veterans Administration Hospital, Menlo Park, Calif.

FIGURE 1
Postulated Routes of Synthesis of DMT and 5-Methoxy-DMT

DOES DMT PRODUCE SIGNIFICANT SCHIZOPHRENIC-LIKE SYMPTOMS?

In 1956 Szara (9) found that the effects of DMT on 20 normal volunteer subjects were similar to those of LSD and mescaline: visual illusions and hallucinations, distortions of spatial perception and body image, speech disturbances, and euphoria. A striking finding was that the effects of DMT began within 5 minutes and ended within 1 hour after injection. Similar results have since been reported by Rosenberg and associates (10) and Turner and Merlis (5).

In order to reexamine the psychological effects of DMT and to correlate them with pharmacokinetic aspects, we administered .7 mg/kg of DMT intramuscularly to 15 male volunteers. Each subject was an experienced user of LSD, mescaline, or other psychedelic substances who expressed an intention to continue using these agents in the future. All subjects were interviewed by two psychiatrists and were given a complete medical history and examination prior to testing in order to ensure the absence of psychiatric and physical impairment.



Like previous investigators, we found that DMT was a hallucinogen with rapid action and a short duration of effect. Psychological changes were evident within 5 minutes of injection, peaked at about 10 to 15 minutes, and ended within 45 to 120 minutes. The major psychological effects are shown in table 1. The subjects became so uncommunicative and withdrawn during the drug experience that we were forced to inquire about the subjective effects with simple "yes-no" questions. Although all subjects reported visual distortions and illusions, these were color or spatial distortions rather than formed visual hallucinations. Only 1 subject reported an auditory hallucination, a "buzzing bee" in his ear. We did not observe formal loosening of associations, although several subjects seemed to have thought blocking. Two subjects had paranoid symptoms that lasted less than an hour.

These psychological changes were accompanied by

TABLE 1
Subjective Effects of DMT Experienced by 15 Normal Volunteer Subjects, in Percents

Subjective Effect	Percent
Visual hallucinations	100
Hallucinations with eyes closed	100
Movement of surroundings	93
Difficulty talking	93
Difficulty describing feelings	93
Relaxation	93
Difficulty concentrating	93
Colors seem brighter	87

Hallucinating "real things"	27
Paranoia	20
Auditory hallucinations	7

FIGURE 2
Mean DMT Concentrations in Whole Blood Following Injection of DMT in 15 Normal Volunteers

mydriasis, tachycardia, and increased blood pressure. Blood levels of DMT (see figure 2), assayed by a gas chromatographic-mass spectrometric (GC-MS) isotopic dilution technique, closely paralleled the psychological and autonomic changes (11). Peak concentrations of DMT, which averaged approximately 100 ng/ml,

were reached about 10 to 15 minutes after injection; the concentration then fell rapidly to baseline, undetectable levels within about 45 to 120 minutes after administration.

IS DMT FOUND IN MAN?

Several investigators have reported the presence of DMT in blood and urine of psychiatric patients (see table 2). Positive reports were more common with the earlier, less specific methods of analysis than with the later GC-MS techniques. Although DMT has occasionally been identified by GC-MS techniques in some subjects, the concentration has been extremely low. Also, the presence of DMT has not been reported more frequently in patients with particular diagnoses or in psychiatric patients in general compared with normal controls. The origin and significance of the identified DMT is unknown. Although it might reflect endogenous synthesis, it could also result from diet, bacterial products, laboratory error, or other sources.

IS THE PRECURSOR OF DMT PRESENT IN MAN? CAN DMT BE SYNTHESIZED IN MAN?

As figure 1 indicates, DMT is thought to be synthesized from tryptamine in a reaction catalyzed by an *N*-methyltransferase (NMT). Tryptamine is reportedly present in human lung and elsewhere (26). NMT activity has been reported in human brain (27, 28) and blood (29), but its highest activity and specificity is in human lung (30). Mandel and associates (30), using GC-MS techniques, demonstrated in vitro conversion of *N*-methyltryptamine to DMT in human lung. Wyatt and associates (31) and Murphy and Wyatt (32) have found that MAO activity in platelets is low in some schizophrenics compared with control subjects, and that this defect may be genetically determined. Low MAO activity may lead to elevated concentrations of tryptamine, which would favor the synthesis of DMT.

In vivo human synthesis of DMT has not been convincingly demonstrated to date. We studed 1 male chronic schizophrenic patient before and during administration of 45–60 mg/day of the MAO inhibitor phenelzine. Although the patient was more hallucinatory and autistic on phenelzine than he had been during the placebo period, DMT concentrations in venous blood did not change from their very low placebo values (approximately .07 ng/ml). We also studied another male schizophrenic patient before and during treatment with 20 g/day of L-tryptophan, the biosynthetic precursor of tryptamine. Again, there was no change in blood DMT concentration. The patient's clinical condition was not altered by L-tryptophan.

IS DMT SYNTHESIZED OR METABOLIZED DIFFERENTLY IN SCHIZOPHRENICS THAN IN CONTROLS?

Synthesis of DMT in man has yet to be conclusively demonstrated, and little knowledge currently exists on the metabolism of DMT in schizophrenics compared with normal control subjects. Szara (9) suggested two major routes of metabolism of DMT: 1) dealkylation and oxidative deamination, leading to indole-3-acetic acid and 2) 6-hydroxylation followed either by glucuronide formation of 6-hydroxy-DMT or by dealkylation and oxidative deamination leading to 6-hydroxyindoleacetic acid (33). To our knowledge, there have been no studies comparing the concentrations of these metabolites in schizophrenics and controls.

Our recent study of the effects of DMT on volunteer subjects (11) suggested that the drug is rapidly metabolized. Assuming that DMT is distributed equally throughout the blood, we could account for only about 2% of the administered dose at the time of the peak blood concentration. Moreover, less than .01% of the administered dose was found in urine within 24 hours, and most of that amount was excreted within the first 6 hours.

Thus the failure of various investigators to find elevated concentrations of DMT in venous blood or urine of schizophrenics may be explained by the rapid metabolism of this compound. If DMT is actually formed by lung NMT, then schizophrenia is a lung disease, and DMT may be transported directly from lung to brain via the arterial system. Once DMT is exposed to liver, kidney, or muscle, it may be so rapidly metabolized that measurable concentrations cannot be detected in venous blood.

DOES TOLERANCE TO DMT DEVELOP?

Since schizophrenia is a clinical syndrome that lasts for weeks to months in its acute forms and for years to decades in its chronic forms, a biochemical theory must be able to explain long-term symptoms. The issue of tolerance has been a major problem in the schizotoxin theory of schizophrenia. Tolerance to LSD, mescaline, and psilocybin develops rapidly in man and animals, for some if not all behavioral effects.

In our initial efforts, we found that tolerance did not develop to unconditioned behavioral and EEG effects of DMT in cats administered DMT twice daily for 15 days or every 2 hours for 24 hours (34). Also, lack of behavioral tolerance has been reported in squirrel monkeys given DMT once daily for 38 days (35).

More recently, we studied the issue of tolerance in 4 normal male volunteers who received 0.7 mg/kg of DMT intramuscularly twice daily for 5 days. Repeated administration did not consistently alter the peak blood concentration of DMT; autonomic changes in pupil size, pulse, or heart rate; the number of psychological items changed in a psychological scale; or the frequency of errors in a test requiring the subject to cross out a specific number in a list of random numbers. Three of the 4 subjects reported diminished subjective "highs" on a scale of 0 to 10 after two to four injections of DMT, but their subjective responses were variable from trial to trial and did not indicate a general loss of responsiveness to DMT. Rather, these subjects exhibited a variable or aperiodic partial tolerance to DMT. This pattern is reminiscent of Koella and associates' report of a cyclic change in ambulation produced by LSD in goats (36). Further studies, including longer or more frequent trials with DMT, are necessary to fully evaluate this phenomenon.

This type of variable tolerance has also been reported recently by Kovacic and Domino (37), who studied the suppressive effects of DMT on the operant behavior of appetitively conditioned rats who were given DMT every 2 hours for periods of up to 21 days.

Böszörményi and Szara (38) reported that schizophrenics are less sensitive to the effects of DMT than controls. If schizophrenics do show diminished responsiveness to DMT, this may result from increased metabolism or variable tolerance resulting from long-term endogenous synthesis of DMT.

DO NEUROLEPTICS INHIBIT THE SYNTHESIS, INCREASE THE METABOLISM, OR ANTAGONIZE THE EFFECTS OF DMT?

Although the evidence is currently incomplete, there are data suggesting that antipsychotic medications may inhibit the activity of NMT. Axelrod (39) has suggested that chlorpromazine might have this effect. Moreover, a dialyzable inhibitor of NMT has been reported in bovine pineal gland (40), which is an interesting finding because Bigelow (41) obtained favorable clinical results in some schizophrenic patients with an aqueous extract of bovine pineal gland. Some dimethylated metabolites of chlorpromazine have also been reported to be competitive inhibitors of NMT (42). Thus it is conceivable but unproven that antipsychotic drugs inhibit the synthesis of a methylated schizotoxin. Little is known, however, about the influence of antipsychotic medications on the metabolism or behavioral effects of DMT.

DISCUSSION

Although the DMT model of schizophrenia remains attractive, most of the positive evidence is indirect, supporting the plausibility rather than the reality of the model. DMT does produce striking psychological changes in normal subjects, the enzymes and precursors are present to synthesize it in vitro in human tissue, it has been found occasionally in man, and tolerance to its behavioral effects is incomplete. Moreover, effective antipsychotic treatments may conceivably interfere with the synthesis of DMT.

On the other hand, significant differences in DMT concentrations in schizophrenics versus controls have not been proven, in vivo synthesis of DMT in man has not been demonstrated, and the psychological changes induced in man by DMT do not closely mimic the clinical symptoms of schizophrenia. When psychological changes have been produced in normal subjects, this has been with DMT blood concentrations 50 to 100 times greater than those in the few schizophrenic patients in whom DMT has been identified.

Arguments can undoubtedly be produced to refute each of these objections. The psychological effect of DMT in normal individuals probably should not be expected to mimic schizophrenia. After all, the volunteer knows what is happening to him when the experimenter administers DMT, but DMT is (hypothetically) synthesized endogenously in schizophrenic patients. The data on DMT in blood and urine may be of dubious relevance in view of its rapid clearance from blood and its failure to appear in appreciable amounts in urine.

Like any good scientific theory, the DMT model of schizophrenia will ultimately live or die by the data that it heuristically generates. We hope that, within the foreseeable future, forthcoming data will give this theory either a new lease on life or a decent burial.

Recent Developments in the Drug Treatment of Schizophrenia

BY JOHN M. DAVIS, M.D.

The author reviews six topics relevant to the drug treatment of schizophrenia. The quantitative effectiveness of promazine is of interest with respect to the structural models of the phenothiazines and the dopamine theory of schizophrenia. The quantitative effectiveness of antipsychotic drugs is also important in evaluating new agents and therefore relevant to a discussion of two newly released neuroleptics, molindone and loxapine. The author's discussion of high-dose treatment for typical acute schizophrenics or treatment-resistant patients reviews the available data and calls attention to the fact that these areas of pharmacologic research have not received sufficient attention.

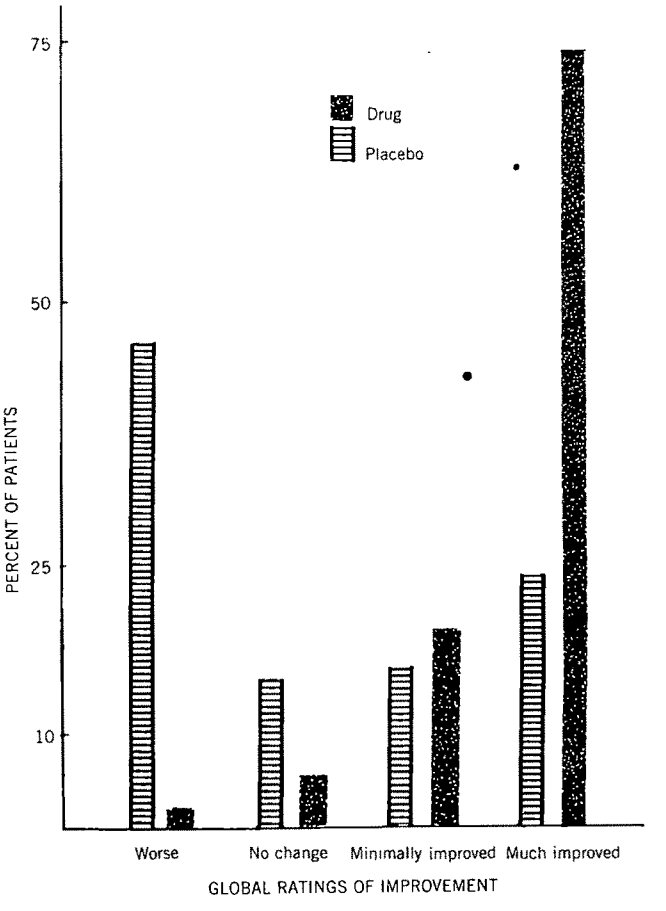
SOME RECENT DEVELOPMENTS in the drug treatment of schizophrenia are relevant to six problems of practical importance: 1) the effectiveness of the antipsychotic agents as compared with placebo in the treatment of schizophrenia; 2) indications for use of antipsychotic drugs; 3) the usefulness of massive doses in improving clinical response in typical acute schizophrenia; 4) drug treatment of the phenothiazine-resistant patient; 5) phenothiazine effectiveness and molecular models; and 6) the effectiveness of two new neuroleptic agents, molindone and loxapine. Since the use of the intramuscular depot drugs such as fluphenazine decanoate (a useful strategy for schizophrenic patients who tend to forget to take their pills and an important addition to clinical therapeutics) has already been reviewed recently in the *American Journal of Psychiatry* (1), I will limit the content of this paper to avoid redundancy.

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Davis is Director of Research, Illinois State Psychiatric Institute, 1601 West Taylor St., Chicago, Ill. 60612, and Professor of Psychiatry, University of Chicago, Pritzker School of Medicine, Chicago, Ill.

QUANTITATIVE MEASUREMENT OF NEUROLEPTIC EFFICACY

In a statistical analysis of the efficacy of any medication, it is important to distinguish the quantitative magnitude of an effect from the statistical probability that it may occur by chance alone. For example, one could find a very high correlation of marginal statistical significance because of a small sample size or an extremely low correlation that is highly significant because it is based on a large sample. The real issue is the magnitude of the neuroleptic effect, i.e., the degree of difference in improvement or deterioration between neuroleptic drug and placebo groups, regardless of sample size.



In the National Institute of Mental Health (NIMH) collaborative study on the treatment of acute schizophrenics (2, 3), many patients in the placebo group deteriorated to such a degree that they had to be removed from the study (2, p. 248 [table 2]). In any drug study one important index of drug-placebo differences is the number of patients whose conditions deteriorate to such a degree that they must be removed from the study or who improve to such a degree that they can be discharged. The NIMH collaborative study also evaluated the patients who completed the trial as to whether they were much improved, minimally improved, unchanged, or worse (2, p. 252 [figure 2]).

Figure 1 presents these data, combining the number of patients who deteriorated with the global evaluation of deterioration or improvement on drug or placebo. The magnitude of the drug effect can be seen in this figure without recourse to mathematical statements. One can see that three-fourths of the patients benefitted substantially from antipsychotics during the six-week trial and virtually no patients deteriorated, whereas nearly 50% of the placebo group deteriorated.

Quantifying these impressions presents a somewhat more subtle problem. The total drug-placebo difference can be estimated by assigning the arbitrary numbers 0 and 1 to drug and placebo and the numbers 2, 1, 0, and –1 to the different degrees of improvement. One can then calculate from this kind of data a rank order correlation coefficient. (Because of the ties, the product-moment formula is the appropriate statistic to use.) It should be noted that since the data underlying the arbitrarily chosen numbers are not necessarily at equally distant intervals, no precise estimate of the percent of variance explained by the correlation can be calculated.[1]

In any case, the correlation between therapeutic improvement and whether or not drug or placebo was given would be estimated at about .60. Using parametric statistics, the squared product-moment correlation

FIGURE 1
Doctor's Global Rating of Improvement in Patients After Treatment with Phenothiazines or Placebo

coefficient ($.60^2 = .36$) indicates a percentage of the variance explained by the correlation. Unfortunately, with nonparametric statistics the concept that one's findings explain a particular percent of the variance is somewhat problematic, so we cannot offer this as a quantitative estimate of percent of variance explained in any precise sense other than perhaps as an estimate of the general order of magnitude effect. Parenthetically, it might be added that thioridazine, when used to treat anxiety, explains (through a similar calculation procedure) about 5% of the variance (or a correlation of around .20), a much smaller effect than its antipsychotic effect in schizophrenia.

A somewhat smaller drug-placebo difference was expected in studies of chronic patients, such as maintenance trials on chronic inpatient schizophrenics or on chronic relapsing outpatient schizophrenics. To estimate the order of magnitude of this side effect for the more chronic population, we examined four particularly good NIMH-sponsored double-blind placebo-controlled trials of antipsychotic medication in chronic schizophrenics (2 inpatient [4–6] and 2 outpatient [7–10] studies), and also two double-blind placebo-controlled British trials (11, 12) of chronic neuroleptic medication. Since the distance between the mean drug

[1]It is relevant to add here that even if a quantitative rating scale were used (e.g., BPRS total score) there is no assurance that the different scores or covariance–adjusted final scores would meet such mathematical assumptions as to allow precise estimation of how much variance is explained by the drug-placebo difference.

effect and the mean placebo effect on a scale of improvement increased over time, data must be adjusted to a common study length. The number of patients who deteriorated versus those who maintained their improvement was compared in all of these studies, adjusting to a common study length of 8 weeks. In each case the data from the study were fitted by the least squares method using the equation $R=R_0 \times e^{-kt}$ (R=the number of patients not relapsed; R_0=number of patients that begin in the trial; and t=time). The number of patients in the placebo and drug groups who relapsed or did not relapse at 8 weeks was included in our estimate of the magnitude of the drug-placebo difference in this population. These four numbers constitute a 2×2 table, yielding a phi coefficient (nonparametric estimate of the product-moment correlation coefficient) of .23 (4–12).

INDICATIONS FOR ANTIPSYCHOTIC DRUG TREATMENT

Figure 1 illustrates the fact that a substantial number of patients improve considerably on placebo. This raises the question of what the indications are for antipsychotic drug treatment. Should all schizophrenic patients receive neuroleptic drugs, or will some do better without drugs? This question has not received great attention in the literature. However, one large NIMH collaborative study (13) that investigated 338 patients (74 on placebo and 264 on neuroleptics) correlated a number of variables indicative of process or reactive schizophrenia with differential improvement on drug versus placebo and found that virtually none of these variables predicted response when they were considered individually. Of course, linear combinations of these variables or a higher order combination might have yielded predictors, but even so this is still significant negative evidence. More importantly, though, the lack of evidence here indicates that there is a real gap in our existing knowledge. In many hospitals most schizophrenic patients do receive neuroleptics, so the implicit assumption of many psychiatrists may be that neuroleptics are indicated for all cases of schizophrenia, a somewhat undifferentiated treatment strategy. Conversely, other practitioners proceed as though neuroleptics are to be used only as a last resort after a clear failure of psychotherapeutic methods. A more rational form of therapy would be to base the choice of treatment with antipsychotic drugs on clinical indications defined by research.

MEGADOSE TREATMENT FOR ACUTE SCHIZOPHRENIA

It is clear that one can give massive (mega) doses of such agents as trifluoperazine and fluphenazine that are substantially above the average therapeutic dose. (Doses of chlorpromazine are limited by the sedative side effects that develop, and doses of thioridazine are limited particularly by the development of pigmentary retinopathy, which can occur when gram doses are given.) Would it therefore follow from the clinical information in several studies that treatment-resistant or newly admitted schizophrenics would benefit significantly from massive doses with either more complete or quicker remissions?

Wijsenbeeck and associates (14) performed a double-blind study comparing the efficacy of 60- and 600-mg doses of trifluoperazine in newly admitted schizophrenic patients and found the two treatments to be equally effective. It seems that for the average newly admitted schizophrenic patient, megadoses do not produce substantially greater improvement than regular doses. It is important to remember that, according to an empirically derived equivalence table, 60 mg/day of trifluoperazine is equivalent to about 1 g/day of chlorpromazine and therefore is a high normal dose; 600 mg/day is about 30 times the normal antipsychotic dose (734 mg/day of chlorpromazine) (15).

Conversely, is it possible that there are ineffective doses of antipsychotic agents? Although there are few data from newly admitted patients, there are several studies of subchronic patients (i.e., those who have been ill less than 10 years). One study (16) found that doses of 150–300 mg/day of chlorpromazine were less effective than doses of 600 mg/day, and two other studies (4, 6) showed that 300-mg daily doses of chlorpromazine were less effective than 2000-mg daily doses.

Another study (5) found that a 15-mg daily dose of trifluoperazine (equivalent to 535 mg/day of chlorpromazine) was as effective as 80 mg/day of trifluoperazine (equivalent to 2.8 g/day of chlorpromazine). This probably indicates that 535 mg/day is close enough to the effective dosage range and that an exceptionally high dose will not produce more improvement for this chronic population. However, daily doses of 300 mg are probably below the effective therapeutic range for chronic patients. I have reviewed these studies on dose levels to call attention to this neglected area and to present what little evidence there is available at present on dose-response curves for the antipsychotics.

TREATMENT OF THE PHENOTHIAZINE-RESISTANT PATIENT

Estimates of the dose-response curve should be interpreted in view of our wide clinical experience, which indicates that different patients respond to widely different doses. The explanation of this differential responsiveness undoubtedly lies, at least in part, in the different rates of metabolism of the antipsychotic drugs. In previous studies (17–19), we have found over 100-fold variations of chlorpromazine blood levels between different patients on the same dose of chlorpromazine and a 30-fold variation in different patients

on the same dose of butaperazine. Fast metabolizers may destroy the drug so rapidly that they receive ineffective brain levels unless they are given very high doses, and slow metabolizers may have unusually high brain levels that may be toxic even when they receive normal doses. Some nonresponding patients may be fast metabolizers who would in fact respond if ultra high doses were used. This raises the problem of treatment strategy for the phenothiazine-resistant patient, i.e., the patient who has been treated with adequate doses of antipsychotics but did not improve.

Previous laboratory work indicates that chlorpromazine may be metabolized to a fair extent in the gut wall. To bypass this source of rapid metabolism, we have administered fluphenazine decanoate in high doses to antipsychotic-resistant patients and have achieved good clinical results in patients previously resistant to these drugs. Furthermore, in a double-blind study, Lewis and associates (20) and Curry and Adamson (21) identified such patients by studying their blood level response to a standard dose of chlorpromazine and also found better results in these fast gut metabolizers by using intramuscular fluphenazine rather than oral medication. Although further studies are needed for definitive proof, this initial clinical evidence indicates that perhaps some patients who are resistant to antipsychotic drugs might be tried on parenteral administration. Another way of dealing with fast metabolism may be the use of ultra high doses. Several groups have administered ultra doses (e.g., 1 g of fluphenazine) and reported good results (22–25). However, more evidence is needed, particularly in well-controlled double-blind studies, for definitive proof. There may be indications for megadose treatment in this selected treatment-resistant population in contrast to the random sampling of newly admitted patients where ultra doses do not appear to be helpful for the average patient.

PHENOTHIAZINE EFFICACY AND STRUCTURAL DOPAMINE MODELS

Elsewhere in this section, Dr. Snyder discusses the dopamine theory of schizophrenia. Horn and Snyder (26) noted that there is a structural similarity between the antipsychotic drugs and dopamine receptors. Therefore, it is relevant to compare the clinical efficacy of these drugs with their structural similarity to dopamine receptors. These drugs—except promazine—have equal effectiveness in the treatment of schizophrenia. Since Horn and Snyder proposed an explanation for this in terms of the structural chemistry of promazine, it is relevant to review to what quantitative degree promazine is less effective than chlorpromazine. This finding may become more intelligible in light of Horn and Snyder's observation that the chlorine substituted in the 2-position may selectively orient the chlorpromazine side chain to the A ring. Without this substitution there could be a 50:50 chance of the side chain being thus oriented. It is interesting that promazine does have antipsychotic properties. The two best controlled studies comparing the improvement produced by promazine with chlorpromazine, after subtraction of placebo effect, are those of Kurland and associates (27) and Casey and associates (28). The first study found that promazine produced 51% of the improvement produced by chlorpromazine (27, p.6); in the second study, promazine produced 47% of the improvement produced by chlorpromazine (average improvement at 18 and 24 weeks) (28, p.214). This interesting quantitative comparison, in which promazine appears to be approximately 50% as effective as chlorpromazine in its antipsychotic action, must be viewed from the perspective that the measuring instruments used may not yield additive data.

Much of the relationship between basic biologic science and clinical science rests on correlating the biochemical pharmacology of the drugs with their clinical efficacy. For this reason, it may be instructive in laboratory experimentation to investigate control substances that are structurally similar to effective neuroleptics but do not have antipsychotic properties. Mepazine may be such a drug. It is interesting, for example, that mepazine, a close structural analogue to chlorpromazine, essentially has no extrapyramidal side effects (i.e., the incidence of extrapyramidal side effects with mepazine is equal to that of phenobarbital or placebo) (29–33).

THE EFFECTIVENESS OF TWO NEW ANTIPSYCHOTIC AGENTS

Discussion of Methodology

I will describe certain methodologic points in this discussion of two antipsychotic agents recently introduced on the market. When a new drug is being compared with a standard drug, random error may result in the new drug being found to be equivalent to the standard drug by obscuring a real difference. In addition, a new drug could be found to be equivalent to a standard drug in a very treatment-resistant population—neither drug would show a significant effect. This raises a question regarding the use of statistical tests to rule out false-positive results. Is a new drug found to be falsely equivalent to the standard drug for the above reasons?

Cohen (34) discussed the question of what statistical power is necessary in order to rule out these false-positive (type 2) errors, with the probability of also ruling out false-negative (type 1) errors. In order to do this, it is necessary to have a statement of the treatment effect that I am defining here as the statistical difference between drug and placebo. Assuming our admittedly imprecise estimate reflects the magnitude of the true treatment effect, we can estimate how many patients should be studied in a new drug versus standard drug trial in order to state at the 99% confidence level for both type 1 and type 2 errors that a new drug is in fact

different from the standard drug. At the same time we can keep our statistics sensitive enough to detect a real drug difference, holding the probability of both types of error to the .01 level. Our estimate is that in a maintenance trial 400 patients are needed for this purpose.

Clinical Aspects

Recently two new antipsychotic agents of different structural classes have been introduced on the market. Molindone (Moban) is the first antipsychotic agent that belongs to the indole category and is chemically quite separate in structure from the previous classes (phenothiazines, thioxanthenes, and butyrophenones.). Since molindone blocks amphetamine-induced stereotypic behavior in animals (an abnormal movement disorder mediated by dopamine) and also causes extrapyramidal side effects, it can be inferred that it is probably a dopamine receptor blocker.

The principal evidence that molindone is an effective antipsychotic comes from a very carefully controlled study performed by Clark and associates (35) that compared molindone, chlorpromazine, and placebo. Molindone was clearly superior to placebo on global rating scales of both physician and nurse and on the BPRS and NOSIE scales. Chlorpromazine, as expected, was also superior to placebo.

There are a total of six controlled studies (35–40) with approximately 200 patients that found molindone approximately equal to the standard drug: it was slightly superior in one study, equal in three, and slightly inferior in two. Since *none* of these differences were statistically significant and since the small, minor drug-placebo differences were approximately normally distributed around the standard drug, the empirical data indicate that molindone is approximately equally as effective as the reference antipsychotic. However, in view of the previously mentioned power considerations, too few subjects have been studied to infer that molindone is more effective than placebo, as its similarity to a standard drug may be due to random error (or use of a treatment-resistant population). Despite this problem, these results are consistent in direction with the work of Clark and associates (35), who found molindone to be superior to placebo. In addition, molindone has been used in studies with both acute and chronic schizophrenic patients and in short- and long-term use and in two further comparison studies that (although they suffered from such methodologic limitations as inappropriate statistical analysis) also suggested that molindone was approximately equal to standard drug. Qualitatively, molindone produces roughly the same antipsychotic spectrum of action as the standard neuroleptics. It has the usual antipsychotic effect on schizophrenic symptoms, reducing their intensity with a similar time course, and it also has the prophylactic properties of the other antipsychotics. Whether there are minor differences in its spectrum of action will have to be determined in further studies. Molindone generally has the same range of side effects as the phenothiazines, i.e., extrapyramidal and autonomic side effects. Molindone does not inhibit the norepinephrine uptake pump; therefore, unlike chlorpromazine, it would not interfere with the hypotensive action of guanethidine. Molindone does not cause weight gain.

The other recently introduced drug is loxapine (Loxitane). This drug represents another new chemical category of antipsychotics; in its chemical structure, it is a dibenzoxapine. Since loxapine is active in dogs in antagonizing apomorphine-induced emesis, it may also be a dopamine receptor blocker.

The best evidence for the efficacy of loxapine has been provided by the clinical investigations of Clark and associates (41, 42); in this case, these researchers performed three carefully done, well-controlled, double-blind studies. The first compared loxapine, chlorpromazine, and placebo in chronic schizophrenics; the second compared loxapine, trifluoperazine, and placebo in newly admitted schizophrenics; according to a personal communication from M.L. Clark, the third study was a dose-responsive curve of loxapine. In all three studies loxapine was clearly (statistically significantly) superior to placebo in producing improvement in schizophrenia. In addition, Van Der Velde and Kiltie (43) found loxapine superior to placebo. Selman and associates presented data at a scientific exhibition at the 128th annual meeting of APA (Anaheim, Calif., May 5–9, 1975) that also suggested that loxapine was statistically superior to placebo.

Of the 15 studies comparing loxapine to standard neuroleptics, 12 found loxapine essentially equal to standard neuroleptics (41–53, and a personal communication from H. Kiltie). However, Shopsin and associates (45) found loxapine slightly inferior to standard neuroleptics, and Steinbook and associates (46) found it superior to standard neuroleptics in some but not all measures. Filho and associates (53) found loxapine more effective than thiothixene in younger but not older patients. Charlalmpous and associates (44) found loxapine less effective than thiothixene. Thus, several studies had some evidence that loxapine was slightly superior and many found it equal to a standard drug, but if the results of Charlalmpous and associates are also considered, loxapine is almost precisely equal to the standard drug in its antipsychotic action.

In this series of 15 studies of loxapine, about 600 patients were studied under controlled conditions. Making the assumption that the drug-placebo difference is such that it would explain 5% of the variance, according to the power analysis for sample size already discussed, this sample size would be sufficiently large to detect that the drug was not inferior or superior to standard drug with the probability of .01 for both type 1 and type 2 errors. This sample size is thus probably sufficient to detect a true difference between loxapine and the standard neuroleptic.

There is a final relevant methodologic point to be made here. In combining data from many studies comparing two similar drugs (new versus standard), the new drug will be better than the standard at some

times and inferior at other times by chance alone, generally to statistically insignificant degrees. In making such data combinations, if one fails to mention several of the studies in which a new drug is slightly inferior to standard, the comparison will tilt in a direction that makes the new drug appear slightly superior to standard. In other words, eliminating one tail of the distribution biases the sample to the opposite tail. Therefore, it is very important to include the study by Charlalmpous and associates (44) in any compilation, even though precise quantitation is not possible. Thus 5 out of 6 placebo-controlled trials and the combined data of 15 loxapine versus standard neuroleptic investigations indicate that loxapine is exactly equivalent to the standard neuroleptic and superior to placebo. Loxapine has the same range of side effects as other antipsychotics (extrapyramidal, autonomic, and sedative), and is similar in this respect to trifluoperazine, the reference antipsychotic used in many of the trials.

CONCLUSIONS

Since it is possible that a new class of antipsychotic agents would help a treatment-resistant patient, a trial of these agents as well as a high dose standard drug or intramuscular depot fluphenazine are possible therapies. In addition, there is merit in psychiatrists gaining clinical experience by using new agents for new patients so that the helpful properties of the compounds can be discovered.

EDITORIAL

An Opportunity to Stimulate Self-Evaluation and Learning

SINCE 1969 the American Psychiatric Association, well ahead of many other medical specialty organizations, has been offering its members an opportunity to observe and improve their clinical skills through the Psychiatric Knowledge and Skills Self-Assessment Program (PKSAP). Two programs have been offered to APA members—the first in 1969 and the second in 1972. The third program will be available to the membership in April of this year.

Over 6,700 psychiatrists participated in PKSAP-I and more than 9,800 in PKSAP-II. Since PKSAP-II was offered, the entire medical profession has become alerted to the interwoven issues of lifetime education, government supervision, and the responsibility professional organizations must accept vis-à-vis the constant updating of knowledge by their members. Currently 22 medical associations are offering self-assessment programs to their memberships.

From lessons learned in the first two self-assessment programs an entirely new PKSAP has been formulated. Members of the development committee were chosen to represent all geographical areas and specialty concerns within APA; the area councils and district branch presidents recommended members, of whom 100 contributed to the development of the program. Also, the program has been evaluated for its relevance, clarity, and accuracy by a representative group of psychiatrists.

PKSAP-III has been developed as a learning experience for the individual psychiatrist that will allow him to assess his competence and application of knowledge in the present state of our field. It covers the widest possible spectrum of psychiatric concerns, including personality development and functioning, child psychiatry, diagnostic techniques, social and behavioral science data relevant to psychiatry, psychopharmacology, biological and somatic treatment, psychotherapy and psychoanalysis, group therapy techniques, psychiatric liaison concerns, and psychophysiological processes.

PKSAP-III includes 200 multiple-choice questions that cover a range of psychiatric concerns and levels of competence and 6 patient management problems that lead the participant through the clinical decisions necessary for handling the cases described. One of the 6 clinical cases is presented on cassette tape. To stimulate further learning by the participant, the answers to the items will include one or more literature references. The format of PKSAP-III is an attractive one that can be utilized conveniently by the individual psychiatrist as he or she wishes and in as much time as necessary.

As has been done successfully in the past, APA will maintain absolute confidentiality in regard to individual results. However, each participant will have an opportunity to compare his or her performance with others practicing in a similar area or subspecialty (e.g., psychotherapy, administrative psychiatry, and hospital psychiatry) through selected group evaluations. In addition to the report of scores and other feedback, the participant will receive a certificate acknowledging participation in the program.

It is the hope of the PKSAP Steering Committee that each member of the Association will expand his psychiatric knowledge and ability by participating in PKSAP-III. We also hope that this new program will be utilized by district branches and other psychiatric groups in imaginative ways to engage our membership in incentives toward continuing education, a critical concern for psychiatrists. Through the program the individual psychiatrist will be able to evaluate his personal strengths and weaknesses, and district branches and area councils will be able to develop more relevant and effective continuing education programs based on the broad trends that emerge from the program. With our participation in PKSAP-III, the principles of voluntarism and independence—so important to us as psychiatrists—can be furthered at the same time that we support a valuable program of continuing education that will enhance our knowledge of new developments and maintain the high standards of our specialty.

SIDNEY L. WERKMAN, M.D.

Dr. Werkman is Chairman of the PKSAP Steering Committee and Coordinator of Undergraduate Psychiatry, University of Colorado Medical Center, Denver.

The Educational Objectives of a Psychiatric Residency Program

BY JOEL YAGER, M.D., AND ROBERT O. PASNAU, M.D.

The authors present a statement of the specific educational objectives of their psychiatric residency program. This statement is designed to help residents keep in focus the central tasks of their training and to provide the faculty with an organizing matrix for curriculum development. Through such specific delineation of their objectives, residency programs can also contribute to a clarification of the specialty.

CONFUSION ABOUNDS ABOUT the proper role of the psychiatrist and the legitimate arena of psychiatric activity (1–3). Psychiatric residents are acutely aware of this state of affairs and sometimes have great difficulty in knowing where to focus their attention (4). Several authors (5–8) have traced some of the emotional problems of psychiatric residents to the lack of clear goals in their educational programs. To counteract the tendency toward professional identity diffusion and to help residents keep the central tasks of training in focus, we have set forth specific educational objectives for each area of the residency at the University of California, Los Angeles. In this way we have operationally defined what we believe to be the core of the psychiatric specialty as a body of skills and knowledge. Our residents have found the delineation of the program's expectations to be helpful, and training directors and residents in other programs have requested that our statement be made more widely available.

Core educational objectives have been developed for the first two years of the residency. In the third year residents are encouraged to pursue their individual areas of interest. During the core period residents are expected to become competent in skills and familiar with specific areas of knowledge. These areas of ability and expertise should continue to grow through subsequent training and experience. The list is not intended to be exhaustive or exclusive but to serve as a guideline for study and professional development; although it appears to be comprehensive, it is not meant to deter interest in other aspects of psychiatry.

Dr. Yager is Assistant Professor in Residence and Director of Residency Education, UCLA Neuropsychiatric Institute—Brentwood Veterans Administration Hospital Residency Program, and Dr. Pasnau is Associate Professor in Residence and Chief, Consultation-Liaison Service, Department of Psychiatry, School of Medicine, University of California, Los Angeles, Calif. 90024.

FIRST-YEAR EDUCATIONAL OBJECTIVES

Our first-year program consists of inpatient, day hospital, and emergency psychiatry services, as well as some outpatient and aftercare experiences in adult psychiatry. All residents have completed a prior internship. Seminars on basic psychiatry and the psychiatric literature are included in the curriculum.

Skills

By the end of the residents' first year of training we expect them to be able to do the following:

1. Conduct a comprehensive psychiatric interview.
2. Make use of appropriate laboratory examinations, psychological testing, and other consultations as indicated in the workup of psychological problems.
3. Conduct a family interview.
4. Make accurate psychiatric diagnoses and thorough appraisals of the presenting problems.
5. Formulate a treatment plan and implement it through personal effort and appropriate referral (triage and disposition).
6. Use all psychopharmacological agents well.
7. Conduct supportive therapy with increasing awareness of dynamic issues.
8. Have some understanding of the assumptions and values of dynamic, insight-oriented psychotherapy and begin to apply these principles in clinical work.
9. Become aware of their countertransference problems and personal idiosyncrasies as they influence interactions with patients and begin to learn to deal with them constructively.

10. Work harmoniously within a milieu together with nurses, social workers, psychiatric technicians, and other mental health personnel in information gathering, treatment planning and implementation, and cotherapy; simultaneously learn from others and contribute to their development.
11. Conduct an inpatient group therapy meeting.
12. Administer electroconvulsive therapy when required.

Knowledge

By the end of the residents' first year of training we expect them to be able to discuss the following:
1. The theory and nature of both individual and family interview techniques.
2. The nature of psychiatric data, including phenomenology and frames of reference.
3. Indications, values, and limitations of psychological testing.
4. Methods for distinguishing between organic and functional processes.
5. The differential diagnosis of psychiatric syndromes with appropriate criteria.
6. Evaluation and management of psychiatric emergencies.
7. Patients' rights, indications for involuntary psychiatric hospitalization, and other basic legal issues.
8. Indications and contraindications for full hospitalization, day hospitalization, family intervention, crisis intervention, supportive psychotherapy, behavior therapy, intensive long-term dynamic psychotherapy, group psychotherapy, and ECT.
9. Indications and contraindications for common psychopharmacological agents, as well as dosages, side effects, and drug interactions.
10. Alternative etiological explanations for the psychoses.
11. Basic psychoanalytic concepts.
12. Basic concepts of family organization and communication.
13. Basic principles of learning theories.
14. Basic concepts of group dynamics.
15. Basic concepts of social psychiatry and epidemiology, including concerns and treatment issues with specific ethnic, minority, and disadvantaged populations.
16. A perspective on the different psychotherapeutic schools of thought.
17. Neurobiological basic science, including genetics; biogenic amines; the anatomy, physiology, and pathology of the limbic system; sleep physiology and pathology; and memory.
18. How to critically evaluate the merits and limitations of scientific literature.

SECOND-YEAR EDUCATIONAL OBJECTIVES

The second-year program consists of assignments to consultation-liaison, child psychiatry, and adult outpatient services. Some patients are followed throughout the residency, and new cases are added as indicated. A weekly clinical neurology seminar covering pertinent neurological topics, a seminar in psychophysiological medicine, and a child psychiatry seminar are included in the curriculum. In addition, during the second year the resident continues to develop skills in evaluation and in brief and long-term treatment of individuals, couples, families, and groups. Increasing attention is paid to dynamic issues in psychotherapy and the immediate environment of the doctor-patient interaction including process, countertransference, specific techniques of intervention, and nonspecific effects of the psychotherapy process.

Consultation-Liaison

Skills. By the end of the residents' rotation on consultation-liaison psychiatry we expect them to be able to do the following:
1. Assess the specific intentions of the referring physician for any given request for consultation.
2. Conduct a comprehensive interview of a physically ill patient and a thorough assessment of each case, making appropriate use of information from the referring physician, other hospital personnel, the hospital chart, and the patient's family.
3. Construct a comprehensive formulation of the patient's problems that includes attention to the life setting and specific circumstances leading to the illness and the request for consultation; the present and past significance of the illness and problems, including primary impact and secondary effects on the patient and significant others; psychosomatic and somatopsychic considerations; and the specific influences of the patient's personality on the manifestations of the illness and illness behavior.
4. Define and implement appropriate interventions, addressing the problems that initiated the request for consultation.
5. Undertake the psychotherapeutic treatment, for an extended period of time, of at least one dying patient and one patient with a psychophysiological illness.
6. Effectively communicate with the referring physician, both verbally and through concise, nontechnically worded notes, about the assessment, offering practical suggestions for management. These suggestions may include how the physician might interact with and counsel the patient and his family; ward management by the hospital staff; other environmental manipulation; the appropriate use of psychopharmacological agents in the physically ill; and further recommendations for referral, disposition, and treatment.
7. Develop a good liaison relationship with physicians, nurses, social workers, and the other staff on the service to which the resident is assigned and, using consultation models of community psychiatry, help assess and meet the needs of the staff as mental health educator, facilitator, and resource person.

Knowledge. By the end of the residents' rotation on consultation-liaison psychiatry we expect them to be able to discuss the following:

1. Models of consultation.
2. Social psychology of patient role behavior.
3. Psychological aspects of stress, coping and adaptation, including the dying process, bereavement, transition states, and life crises.
4. Psychiatric interventions in liaison settings.
5. Psychosomatic psychopharmacology.
6. Specific syndromes of special importance in liaison settings, including conversion reactions, pain, gross stress reactions, postpartum psychiatric problems, postoperative psychoses, psychoses in the intensive care unit, psychiatric evaluations for special medical procedures, compensation neurosis, and malingering.
7. Theories of psychosomatic contributions to the pathogenesis of illness.

Child Psychiatry

Skills. By the end of the residents' rotation in child psychiatry we expect them to be able to do the following:

1. Conduct a thorough evaluation of children and their families, properly assessing the nature and significance of presented problems.
2. Appropriately use psychological and physiological assessment techniques to augment the clinical evaluation.
3. Work as a team with psychologists, social workers, and other professionals to obtain a complete evaluation and to formulate appropriate interventions.
4. Appreciate the dynamic and developmental aspects of disturbing behavior in children and adolescents and the extent to which those behaviors are responsive or refractory to environmental contingencies.

Knowledge. By the end of the residents' rotation in child psychiatry we expect them to be able to discuss the following:

1. Principles of the evaluation of children and their families.
2. Major theories of child development, including psychodynamic, cognitive, and biological issues.
3. Common psychiatric problems of childhood and current concepts in the classification of childhood disorders.
4. Mental retardation, including evaluation and treatment planning.
5. Adolescence, with a focus on personality developmental issues.
6. Principles of intervention in child and adolescent psychiatry.

Adult Psychiatry

Skills. By the end of the second year we expect the residents to be able to treat individuals, couples, families, and groups as indicated, with supervision.

Knowledge. By the end of the residents' second year of training we expect them to be able to discuss the following:

1. Alternative theories of therapy, including basic assumptions, indications, and contraindications for the use of different psychotherapeutic techniques for brief or long periods of time, as well as something about available outcome evidence.
2. Characteristics of and explanations for neurotic, characterological, and borderline conditions.
3. Psychiatrically pertinent aspects of neurology.

DISCUSSION

The educational objectives we have outlined are not meant to be static. They are intended to be rethought, updated, and altered, reflecting the evolving perception of the psychiatrist's role by the faculty and residents. Specific educational objectives at other residency programs may differ from ours in substance or in emphasis. Enelow and Weinstein (9) have recently published a report on the detailed goals and objectives for psychiatric residency education. Their objectives and ours, developed independently of one another, both stress mastery of specific areas of knowledge and skill. There are many similarities—and differences—between these two sets of objectives. Such diversity, reflecting psychiatry's broad scope, is commendable. Each program can contribute to a clarification of the specialty by defining its own educational objectives as precisely as possible.

Statements of educational objectives offer advantages to applicants, residents, and faculty. We include the statement in the descriptive material sent to applicants, many of whom have commented favorably that such statements can provide applicants with additional means by which to compare and contrast training programs. The statement is distributed at the beginning of each year to new residents and those continuing in the program as part of the orientation manual and can be referred to when the resident starts a new rotation.

For the faculty, the definition of educational objectives provides an organizing matrix around which both the didactic and clinical experience in the curriculum can be constructed. Seminars and clinical experiences that compete for limited amounts of resident time can be viewed against their potential contribution to the objectives. These objectives also have proven to be useful in the development of assessment procedures for the residents and for the program as a whole.

By enumerating objectives for specific skill and knowledge areas for psychiatric residency education and by using these as a basis for discussion in the profession, residency programs may help to determine the viability and definition of our specialty in the future.

The Effect of Marijuana on Carbohydrate Metabolism

BY M. ALAN PERMUTT, M.D., DONALD W. GOODWIN, M.D., ROBERT SCHWIN, M.D., AND SHIRLEY Y. HILL, PH.D.

The authors observed the effect of marijuana on carbohydrate metabolism in fed and fasting states in chronic marijuana users. They found no hypoglycemia in 7 patients who were given marijuana after fasting for 24–72 hours. They also found no significant difference in carbohydrate tolerance and no hypoglycemia during an oral glucose tolerance test in 10 patients who smoked placebo or marijuana on alternate days. They conclude that marijuana has no effect on carbohydrate metabolism in the fed or the fasted state in well-nourished chronic marijuana users.

BECAUSE OF THE ASSOCIATION between hunger and marijuana smoking in man, early investigators looked for a hypoglycemic effect of the drug; they found none (1–3). These studies did not specify how long before the marijuana was administered the volunteer subjects had eaten. The concentration of glucose in the blood is maintained in sufficient quantities to prevent hypoglycemia predominantly by gluconeogenesis from the liver after glycogen stores have been used up (4). After a period of starvation liver glycogen becomes depleted, and any substance that impairs gluconeogenesis, e.g., alcohol (5), can cause hypoglycemia. An effect of marijuana on gluconeogenesis might be more readily apparent in subjects who had fasted; the effect might be to produce hypoglycemia. For this reason we observed a sample of marijuana users who had fasted for 24–72 hours before administration of marijuana for subsequent hypoglycemia.

The effect of marijuana on carbohydrate metabolism after eating has also not been evaluated. If marijuana potentiates insulin secretion or action, it might produce reactive hypoglycemia 2–5 hours after a meal. We therefore studied the effects of marijuana on carbohydrate tolerance during a 5-hour oral glucose tolerance test.

METHOD

For this study 10 nonobese male volunteers ranging in age from 23 to 31 who had smoked marijuana at least once a week for one year were admitted to the Clinical Research Center of Washington University Medical School the night before the first of our tests was made. These patients fasted overnight. On the morning of day 1 of the study a fasting plasma for glucose and insulin was drawn from each patient, then either 1 g of marijuana containing 1.5% Δ-9-tetrahydrocannabinol

Drs. Permutt, Goodwin, and Hill are with the Washington University School of Medicine, St. Louis, Mo. Dr. Permutt is Assistant Professor, Department of Medicine, 660 South Euclid, St. Louis, Mo. 63110, Dr. Goodwin is Professor of Psychiatry, and Dr. Hill is Research Assistant Professor of Psychiatry. Dr. Permutt is also a Medical Investigator, Howard Hughes Medical Institute, St. Louis, Mo. Dr. Schwin was with the Department of Psychiatry, Stanford University, Palo Alto, Calif., at the time this research was done.

This research was supported in part by Alcohol, Drug Abuse, and Mental Health Administration grants DA-4RG-008 and DA-00282 from the National Institute on Drug Abuse, AA-4732R and Research Scientist Development Award AA-47325 (awarded to Dr. Goodwin) from the National Institute on Alcohol Abuse and Alcoholism, and Clinical Research Center grant RR-00036 from the National Institutes of Health.

The marijuana and placebo for this study were supplied by the National Institute of Mental Health, Alcohol, Drug Abuse, and Mental Health Administration, Rockville, Md.

TABLE 1
Effect of Placebo Versus Marijuana on Plasma Glucose and Plasma Insulin Levels of 10 Chronic Marijuana Users During a Five-Hour Glucose Tolerance Test

Item	Time of Glucose Tolerance Test						
	Start of Test	One-Half Hour	One Hour	Two Hours	Three Hours	Four Hours	Five Hours
	Mean±SEM	Mean±SEM	Mean±SEM	Mean±SEM	Mean±SEM	Mean±SEM	Mean±SEM
Plasma glucose (mg/100 ml)							
Placebo	92 2	156 12	146 14	120 9	90 7	79 5	86 3
Marijuana	89 2	137 9	140 8	122 6	92 6	74 2	86 3
Plasma insulin (μU/ml)							
Placebo	7 1	63 10	70 10	57 14	27 8	7 1	5 1
Marijuana	8 2	64 17	71 16	57 13	26 6	9 1	7 1

(THC) or marijuana placebo with THC removed was administered by smoke inhalation over a period of 15–30 minutes. The smoke was delivered by spirometer, which minimized the loss of smoke into the atmosphere (6). A standard 100 g oral glucose tolerance test was then performed with samples of blood removed from indwelling intravenous needles at the times indicated in table 1. On day 2 at 8 a.m. a repeat oral glucose tolerance test was performed with either placebo or marijuana, alternating marijuana-placebo sequences with placebo-marijuana sequences. Following the second glucose tolerance test, 7 patients were given nothing by mouth for 24–72 hours except water. At 8 a.m. on day 3, marijuana was again administered, and the patients continued to fast for 6–8 hours. Plasma samples for glucose and insulin were obtained at the times indicated in table 2. Plasma glucose was measured by Technicon Auto Analyser, and plasma insulin was measured by double antibody radioimmunoassay with human insulin standards (7).

RESULTS

Administration of marijuana to 6 volunteer chronic marijuana users in quantities sufficient to produce significant behavioral effects had no hypoglycemic effect after 24 hours of starvation (see table 2). One volunteer (patient 7) was starved for 72 hours before administration of marijuana; he also maintained normoglycemia 6 hours later (see table 2). Plasma insulin was appropriately low in all of the patients who had fasted, and marijuana did not stimulate insulin release.

The glucose tolerance of 10 chronic marijuana users was within normal limits following oral ingestion of glucose after smoking placebo (see table 1). Their carbohydrate tolerance was also normal after marijuana was smoked (see table 1). There was no significant difference between the peak plasma glucose level, time of the peak glucose level, low glucose level, total insulin secreted, peak insulin secreted, or time of peak insulin secretion, nor did hypoglycemia occur in any of the volunteers following ingestion of marijuana. We conclude that marijuana smoking had no effect on carbohydrate metabolism in the fed or fasted state in well-nourished chronic marijuana users.

Joint Admission as a Treatment Modality for Problem Drinkers: A Case Report

BY THOMAS J. PAOLINO, JR., M.D., AND BARBARA S. MCCRADY, PH.D.

Joint hospital admission of a married alcoholic and his/her spouse can facilitate treatment of the problem drinker. A case report illustrates the advantages of this approach in giving the staff an opportunity to observe and provide the couple with feedback about their patterns of interaction and to provide specific therapeutic interventions during the joint admission.

THE JOINT ADMISSION described in this paper is a treatment modality that maximally involves the spouse when the alcohol misuser's problems warrant full-time psychiatric hospitalization. Most, if not all, problem drinkers have painfully difficult relationships with significant people in their lives. Spouses of actively drinking alcoholics usually experience major psychological problems (1–6). While the alcoholic's behavior may adversely affect the spouse, the spouse may unknowingly behave in certain ways that either trigger drinking episodes or help to maintain problem drinking (7). Caring for the drunk alcoholic, covering for him at work, etc., may actually reinforce his drinking. Nagging may be an antecedent to drinking bouts. The misuse of alcohol may also indicate the presence of serious conflicts in the marital relationship (8). Therapists therefore have concluded that the spouse should be significantly involved in the problem drinker's treatment program (9, 10).

This research was supported in part by a grant from the Rhode Island Department of Mental Health, Retardation, and Hospitals.

Dr. Paolino is Director and Dr. McCrady is Psychologist, In-Patient Division, Butler Hospital, 333 Grotto Ave., Providence, R.I. 02906. Dr. Paolino is also Assistant Professor of Psychiatry and Dr. McCrady is also Instructor in Psychiatry, Department of Psychiatry and Human Behavior, Brown University, Providence, R.I.

The authors wish to thank Kathleen Catallozzi, R.N., M.S., Ruth Faris, Suzanne Swanson, R.N., the staff of the In-Patient Division of Butler Hospital, and Ben W. Feather, M.D., Ph.D., former Chairman, Department of Psychiatry and Human Behavior, Brown University, and Executive Director, Butler Hospital.

The earliest reports of joint admissions were of disturbed mothers and healthy infants (11). There have been a few reports (12, 13) of the joint admission of severely disturbed psychiatric patients and their normal families, but alcoholism was not mentioned specifically as a problem. Some investigators (8, 14) have conducted research projects in which father–son and brother–brother alcoholic pairs were admitted to research wards in order to permit observation of their interactions. Although alcoholics and their families have been jointly admitted to residential centers (15), to our knowledge there have been no published reports on joint admissions of alcoholics and their spouses to a psychiatric hospital or a medical facility for acute disorders.[1]

The Alcoholism Joint Admission Project is a clinical-research project that was established at Butler Hospital in July 1974. It provides for the admission of both the alcoholic and spouse, who share a bedroom on a community-oriented ward that includes patients of all diagnoses and all ages over 12. The spouse, officially a "guest" of the hospital, is present on the ward as much as possible but continues in his/her outside job. The spouse participates in all relevant ward activities, including daily ward community meetings, treatment team meetings, and supportive occupational and recreational therapy, and talks with ward staff and patients. The patient and spouse also participate in group therapy, which continues after discharge.

The goals of the joint admission are as follows:

1. To give the staff opportunity to observe the couple's interactions.
2. To provide comprehensive feedback to the couple about their patterns of interacting.
3. To integrate the spouse into the milieu so that the spouse has the same opportunity as the problem drinker to experience the closeness and caring of the unit.

[1]After this manuscript was prepared, Steinglass and associates (16) presented a paper on an in-hospital treatment program for alcoholic couples.

CASE REPORT

At the time of admission in February 1975 Mrs. B was a 28-year-old housewife and her husband a 29-year-old crane operator; they have a daughter who was then 4 years old. Mrs. B had had no previous psychiatric treatment before her admission because of progressive alcohol misuse, depression, marital conflict, and severe suicidal thoughts.

Mrs. B, a tall, attractive woman, described in detail a deprived, lonely childhood and adolescence, during which she rarely saw her alcoholic parents. Her father had left home when she was 5 years old, her mother had remarried, and she was raised by her grandmother, who died suddenly 10 years earlier. Mrs. B perceived her grandmother's death as a form of rejection and abandonment and began to abuse alcohol, drinking an average of 12 cans of beer or an equivalent amount of liquor each evening. From ages 18 to 22 her life was unsettled. After graduating from high school she wandered from place to place until the age of 22, when she met her husband. They married 1 year later and have never been separated.

Mrs. B was apprehensive about failing and feared rejection. She had experienced failure in numerous clerical jobs, which again precipitated excessive drinking. Fear of rejection was a constant theme throughout her life and a major antecedent to her excessive drinking.

Mr. B was outgoing, sociable, and had many friends, while Mrs. B had little social involvement with other people. Mrs. B saw this difference in social behavior as a major source of conflict and feelings of inadequacy.

Mr. B, who had 4 brothers, had no personal or family history of psychiatric illness or alcohol abuse.

On admission Mrs. B was cooperative and neatly dressed. She frequently hesitated when discussing emotionally charged material, but her speech was coherent and relevant. Her mood was one of marked sadness and apprehension but was appropriate to her thought content. There were no manifestations of thought disorder or any signs of organic disturbance. She displayed average self-understanding and a firm motivation for treatment of her alcoholism and depression.

Findings from a physical examination, medical history, and laboratory tests showed Mrs. B to be in good health. However, her scores on the Psychological Screening Inventory (17), Multiple Affect Adjective Check List (18), Quantity Frequency Index (19), and the Alcohol Impairment Index (20) were all abnormal. Mr. B's test scores were within the normal range.

During the first week of inpatient treatment Mrs. B lived in the hospital without her spouse. During that time she experienced mild alcohol withdrawal symptoms and developed a strong therapeutic alliance with the ward staff. She often spoke of her marriage, her feelings of rejection, and her compulsion to drink, but she had difficulty giving specific details about her husband's "rejections." This difficulty was clinically important, since, as will be shown later, the joint admission served to provide the ward staff with specific behavioral data clarifying this issue.

Mr. B moved into the hospital during the second week of treatment. The following are some meaningful events observed by the staff.

1. Mr. B threatened to divorce Mrs. B if she became "mentally sick" again. When Mr. B made this threat, the staff immediately interceded and encouraged the couple to talk more about the issue, with the result that there was a significant reduction in the tension surrounding this aspect of Mr. B's thinking and behavior.

2. Mrs. B was extremely jealous and constantly feared that Mr. B would leave her for another woman, when in fact he had always been faithful. Several times, Mrs. B became very distraught when she saw her husband innocently talking with female patients. On these occasions she stormed off to her room, and the staff immediately brought the couple together to discuss the problem. Mrs. B said she felt rejected and that if she were home, she would be turning to alcohol. Mr. B appreciated, perhaps for the first time, the intensity of his wife's insecurity and jealousy. Mrs. B learned how she was misinterpreting her husband's friendliness as infidelity.

3. Some nights Mr. B spent up to 5 hours watching television on the ward and "tuning out" his wife. Again, Mrs. B interpreted this as rejection, got very angry, and told the ward staff that this was another time when she would be drinking excessively if she were not in the hospital. The staff met with the couple as soon as these issues arose. Mr. B became more aware that his excessive television viewing was not only a way of avoiding interaction with his wife but also an antecedent to her alcohol abuse. Mrs. B learned that watching television was not necessarily tantamount to rejection.

4. Mrs. B felt rejected almost every time that Mr. B was not available to listen to and meet her demands. She stated that were she not in the hospital, these would also be times when she would drink to excess. The staff defined and clarified the interactions that were rejecting in contrast to the behavioral patterns of Mr. B that Mrs. B misinterpreted as rejection.

5. Most of the time Mrs. B was shy and timid toward her husband and other people, even when she was angry. The ward staff taught her to be more assertive, and eventually she was able to confront her husband and other people with her feelings without the assistance of staff members.

6. Mrs. B frequently awakened her husband in the middle of the night to "tell him how I was feeling." At these times he immediately sought the staff's help, and they promptly indicated to Mrs. B that she was being unreasonably demanding of her husband's attention and that this behavior tended to drive him away from her. Eventually, with the staff's help, the couple made some agreements to change their behavior. For example, Mr. B agreed to watch television for no more than 2 hours each night if Mrs. B would agree not to awaken him during the night.

DISCUSSION

Mrs. B improved significantly and was discharged to outpatient care after 3 weeks of the joint admission. The following clinical achievements seemed related to the joint admission.

1. The couple used the ward staff to give them continuous feedback about their relationship and how certain aspects of that relationship were directly related to problem drinking.

2. By being in the protective ward environment the couple said and felt things that might have been too frightening outside the hospital. They could express angry feelings as they occurred without worrying as much about losing control of their anger, since, obviously, the ward staff would not allow destructive behavior.

3. Mr. B was able to see that his wife, as well as oth-

er people with serious emotional and behavioral problems, could be helped to overcome these difficulties.

4. The couple were able to remain together and to support each other during the most critical part of Mrs. B's illness.

5. The joint admission made discharge less difficult and shortened the length of hospitalization, since Mr. B was less afraid and more willing to accept and deal with Mrs. B's psychiatric problems, even if they were not completely resolved.

This case history suggests that the joint admission could be a clinically effective treatment modality, replicable relatively easily at other psychiatric inpatient units. However, a more definitive statement on its effectiveness must await the results of an evaluation currently in progress.

At first we conceptualized the joint admission as a means of thoroughly observing the couple in order to better understand the dynamics of their relationship. Experience with 18 joint admissions has led us to conclude that perhaps couples could further benefit from a more structured program focusing on specific behavioral interactions that serve as antecedents to drinking or that actually reinforce drinking behavior.

Some research findings (21–23) have suggested that an operant reinforcement approach can increase the likelihood of successful treatment outcome with couples and with problem drinkers.

However, one of the difficulties frequently encountered in using behavioral approaches to the treatment of couples is the problem of "homework." Although a couple may often be acutely uncomfortable and want to achieve certain behavioral changes, initial practice of this behavioral change is usually difficult for the following reasons.

1. The couple often realize that they do not understand the instructions for homework.

2. The couple do not have the skills to initiate the new behavior.

3. There are both significant reinforcers for the old, undesired behavior and avoidance responses for the new, unknown behavior.

One possible way to facilitate practice and therefore behavioral change would be to initiate treatment within a structured inpatient ward environment that would continuously provide instructions, feedback, and contingent reinforcement for behavior. In treating a couple when one spouse is a hospitalized alcohol abuser, such contingent reinforcement, feedback, and supervised practice would be facilitated by a joint admission.

Chronic Hashish Use and Mental Disorder

BY COSTAS STEFANIS, M.D., ARIS LIAKOS, M.D., JOHN BOULOUGOURIS, M.D., MAX FINK, M.D., AND ALFRED M. FREEDMAN, M.D.

The authors compared 47 long-term users of hashish with a control group of 40 subjects matched for age, ethnic origin, education, etc., in order to determine whether they differed significantly on psychiatric, physical health, and demographic variables. There was a significantly higher incidence of personality disorders, unemployment, and prison sentences in the group of chronic users. However, in contrast to the findings of other researchers, the hashish users did not have organic psychoses, nor did they differ from control subjects in neurologic signs or EEG and echo encephalogram patterns.

THE CONTROVERSY concerning the long-term effects of chronic cannabis use remains unresolved despite numerous publications on the subject (1–3). The long-term behavioral and mental effects of cannabis use are particularly in dispute (4–7). The need for more systematic and controlled studies has been noted (8); to meet this need, we carried out an intensive study of a population of chronic hashish users in Greece. Our study consisted of 1) population identification and comparison with a control sample, 2) experimental assessment of the effects of different strengths of cannabis preparations, and 3) assessment of withdrawal effects. In this report, we will present the results of the population study, which investigated the incidence of mental disorders and the personal and family characteristics of the chronic cannabis users.

Revised version of a paper presented at the 127th annual meeting of the American Psychiatric Association, Detroit, Mich., May 6-10, 1974.

The authors wish to acknowledge the assistance of Drs. C. Miras and C.P. Panayiotopoulos, Ms. A. Kokkevi, Ms. D. Gefou, and Mr. L. Bassiakos of the University of Athens, and Drs. R. Dornbush, J. Volavka, and P. Crown of New York Medical College.

METHOD

Data were obtained by psychiatric examinations and social history inquiries, supplemented by physical and neurologic examinations, psychological assessments, and EEG recordings. The social history inquiry was based on structured interviews with the subjects and family members; the psychiatric assessment included a psychiatric history and a mental status examination following the structured format developed by Mayer-Gross and associates (9). Each case was discussed by the psychiatric team. Psychiatric records were obtained for subjects who had had psychiatric treatment, home visits were made, and information was gathered from local civil authorities (town hall and police). The psychiatric diagnosis was made by consensus, using *DSM-II* (10) criteria.[1]

SUBJECTS

Hashish Users

Our sample of cannabis users consisted of individuals who had used cannabis for more than 10 years and were using it at the time of investigation. Individuals who used other addictive substances, except tobacco and alcohol (social use), were excluded from the study. This included those who were reported to be drunk regularly, who were dependent on alcohol, or whose drinking interfered with their work performance. The presence of incapacitating physical illness or neurologic disease was also a basis for exclusion.

Of 60 cannabis users examined initially, 13 were excluded: 4 for heroin use, 3 for alcoholism, 1 for use of LSD, 1 for inadequate current use of cannabis, and 4 for being above the cut-off age of 58 years. The final sample included 47 male subjects. Of these, 19 were referred by Prof. C. Miras and were part of a pool of chronic cannabis users he had studied previously (11). The rest were recruited by our social services from the community.

The mean age at first use of cannabis was 17 years. Subjects had smoked cannabis an average of three times a day almost every day for 23 years, and they consumed an average of 5 g of hashish each day. An

[1]The study design made blind psychiatric assessment impractical. If we had insisted on blind and structured psychiatric procedures, we would have missed much of the information vital to the purpose of the study.

analysis of hashish described by subjects as being of average strength revealed a 4 to 5% THC content, which corresponds to a mean intake of 200 mg of THC per day.

Control Group

Control subjects were selected by matching requirements in terms of age, ethnic origin, education, place of birth, and family structure. Other criteria included 1) never having smoked cannabis, and 2) smoking tobacco (more than 10 cigarettes a day). Exclusion criteria for alcoholism, illness, etc., were identical with those for hashish users.

An initial 64 subjects were either 1) recruited by social workers from the community in the same fashion as the hashish users, or 2) recommended to the study team by the hashish users as being from similar social circumstances and known not to use hashish. Of the 64, 24 were excluded: 8 for having smoked cannabis at least once, 5 for alcoholism, 4 for being above the cutoff age, 3 for not being tobacco smokers, 2 for central nervous system diseases, 1 for having used heroin, and 1 for having a sibling who was a cannabis user. The final control group consisted of 40 male subjects, 31 derived from community sources and 9 referred by hashish users originally studied by Miras (11).

RESULTS

Personal History Data

The groups were matched for age, education, ethnic origin, place of birth, family history for mental illness, and type of upbringing. There were no differences between the groups in the incidence of neurotic traits during childhood, separation from parents before the 15th year of age, or marital status. Differences were found, however, in the following personal history data.

1. Previous psychiatric treatment: Nine hashish users (19%) had previous psychiatric treatment compared with 2 (5%) of the controls ($\chi^2=3.94$, $p<.05$).

2. Regular military service: Only 26 of the 47 cannabis users (55%) had served regularly in the Army compared with 38 of 40 control subjects (95%) ($\chi^2=17.49$, $p<.001$). Military service is compulsory in Greece, but cannabis use is cause for exemption from service; this difference may thus be related to military criteria. However, personality disorder and psychotic illness are also reasons for exemption from military service.

3. Imprisonment: Twenty-five cannabis users (53%) had been in prison for violations of cannabis laws, compared with 1 (2%) of the controls, who was sentenced for selling hashish ($\chi^2=26.49$, $p<.001$). Additionally, 29 cannabis users (61%), were sentenced for reasons other than cannabis law violations compared with 10 (26%) of the control subjects ($\chi^2=11.76$, $p<.001$). There was no relationship between the amount of hashish smoked and imprisonment for reasons other than cannabis law violations. This relationship was investigated by dividing cannabis users into heavy and moderate smokers on the basis of mean amount of cannabis smoked.

4. Work record: While the two groups did not differ in number of occupations or job changes, 20 cannabis users (42%) were unemployed at the time of the study compared with 6 control subjects (15%) ($\chi^2=7.82$, $p<.01$). Similarly, 12 cannabis users were skilled workers (25%) in comparison with 25 (62%) of the controls ($\chi^2=12.08$, $p<.001$).

Mental Disorders

In psychiatric assessments, psychopathology of some type was defined in 18 of 47 cannabis users (38%) and in 7 of 40 controls (17%) ($\chi^2=4.55$, $p<.05$). Diagnoses included personality disorder, neurosis, and paranoid schizophrenia (see table 1). No subjects exhibited organic psychoses.

The diagnosis of personality disorder was made in 12 of 47 hashish users (25%) versus 3 (7%) of the controls ($\chi^2=4.92$, $p<.05$). Five users were further characterized as manifesting a disorder of the antisocial type, while no control subjects were so diagnosed ($\chi^2=4.51$, $p<.05$). The remaining subjects were further classified among other diagnostic subcategories (paranoid, hysterical, inadequate, etc.). Three cannabis users (6%) were classed as having neuroses, as were 3 control subjects (7%). One control subject was diagnosed as clinically depressed, with no such diagnosis in the cannabis group. Three users (6%) were diagnosed as suffering from paranoid schizophrenia as compared with none in the control sample. On examination, they exhibited loosely organized paranoid delusions unrelated to police persecution for possession or smoking hashish. They neglected themselves and lacked insight. One reported visual and auditory hallucinations. Neurotic traits were prominent in their personalities before they started using cannabis. They started smoking hashish in their teens and the onset of psychosis was many years later, except in the case of 1 subject, for whom possible psychotic symptoms were reported at the age

TABLE 1
Incidence of Psychiatric Disorders

Type of Disorder	Hashish Users (N=47) N	%	Control Subjects (N=40) N	%	Chi-Square Value	Significance
Personality disorders	12	25.53	3	7.5	4.92	p<.05
Antisocial type	5	10.63	0	0.0	4.51	p<.05
Other	7	14.98	3	7.5	1.16	n.s.
Neurosis	3	6.38	3	7.5	0.04	n.s.

Paranoid type	3	6.38	0	0.0	0.00	n.s.
Total	18	38.28	7	17.50	4.56	p<.05

of 14. Two of these 3 users had had prior psychiatric inpatient and outpatient treatment. A positive family history of mental illness was recorded for 2 of the 3.

As our hashish user and control samples included subjects recommended by Prof. Miras, a question of sample bias may be raised, since Prof. Miras has described his subjects as psychopathic (11). However, there was no difference in distribution of mental states between the portion of our sample recommended by Prof. Miras and that recruited from the community.

DISCUSSION

This study indicates a high incidence of psychopathology, predominantly the antisocial type of personality disorder, in a population of chronic hashish users. The subjects, who started smoking cannabis at a young age, were examined after an average of 23 years of hashish use. It is not possible to determine whether their personality structure was the result of their hashish use or whether their preexisting personality was conducive to the continued use of hashish in a culture where its use was proscribed.

It is possible that the absence of any diagnosis of organic psychosis in the hashish users may reflect a selection factor, since the subjects were recruited from the community. However, given the number of years these subjects had used hashish and the large amounts they smoked daily, it is clear that a toxic or organic psychosis is not a usual accompaniment of high-dose, chronic hashish use. Although pneumoencephalography was not carried out, extensive neurologic examinations and laboratory tests (EEG and echo encephalogram) were done in both the users and control subjects; the two samples were indistinguishable in the clinical and laboratory signs of organic mental syndrome (12).

These data do not confirm the reports of cerebral atrophy in cannabis users by Campbell and associates (13) or of organic dysfunction by Kolansky and Moore (14). In both of these studies, the users were younger and reported significantly less use of cannabis of much lower potency for much shorter time periods than the hashish users in the present study. If the clinical observations of these researchers were the result of the subjects' use of cannabis, we would expect to find evidence of cerebral dysfunction in hashish users and differences in the neurologic tests between the chronic hashish users and the control subjects. Because we failed to find such differences, we believe that the observations of Kolansky and Moore (14) and Campbell (13) are not the result of cannabis use.

Some authors (4, 6, 14) have suggested that chronic hashish use induces a specific type of psychosis. The 3 hashish users in our study who were diagnosed as psychotic and classified as paranoid schizophrenics did not exhibit clinical features that could distinguish their condition from schizophrenia; therefore, no conclusions concerning the association of this type of psychosis and chronic cannabis use can be made.

We observed employment differences in the hashish users, both in their employment rate at the time of examination and the quality of the jobs. Although these observations could be interpreted as a facet of an amotivational syndrome, other circumstances such as the prevalence of personality disorder, prison sentences, and the stigma related to hashish smoking may have contributed to this difference (15).

Mania and Bromism: A Case Report and a Look to the Future

BY A. JOSEPH SAYED, M.D.

Mania has not been reported as a manifestation of bromism. This paper describes a manic patient who had an elevated serum bromide level. The author suggests that the possibility of bromide-induced mania should be considered when patients who manifest manic symptoms are evaluated. The implications of the bromide–mania relationship for a better understanding of manic-depressive illness are also discussed.

ALTHOUGH MANY ALTERATIONS in mental function due to bromism have been observed, previous reports have not mentioned the association of mania and bromism. Levin (1) listed four bromide "psychoses": simple bromide intoxication, delirium, hallucinosis, and transitory schizophrenia associated with paranoid symptoms. Previous case reports cite confusion, dementia, depression, agitation (2), disorientation, and paranoid delusions (3) as mental symptoms of patients with bromism. Hoff (4) included sleep disturbances, difficulty in comprehension, exaggerated fears, and visual hallucinations in his list of mental aberrations due to bromide ingestion.

The patient who is the subject of this report presented with typical manic behavior and had an elevated serum bromide level.

CASE REPORT

A 23-year-old man was admitted to the psychiatry service of Cincinnati General Hospital after his second visit to the emergency unit in 2 days. His first visit was prompted when he undressed in front of his mother and attempted to bathe in a wash basin in the family home; he claimed he wanted to bathe because he was dirty after picking tomatoes. He became agitated when his father attempted to restrain him and was brought to the emergency unit, but he walked out before he could be admitted. He was returned the following day. The patient expressed paranoid delusions to the staff of the emergency unit, who felt he was having a "psychotic reaction."

Dr. Sayed is a resident in the Department of Psychiatry, University of Cincinnati College of Medicine, 231 Bethesda Ave., Cincinnati, Ohio 45267.

The author wishes to thank Drs. Barry Blackwell and Walter Stone for their valuable comments on this manuscript.

His parents, with whom the patient lived, gave a history of the patient's increased activity over the preceding 2 months. He had occasionally been eating five or six meals a day, often leaving home at night to purchase additional meals. He regularly drank a carton of soft drinks each evening and ate a candy bar in one mouthful. He sometimes worked two shifts consecutively—one for pay and another "for free." His parents stated that he had been going for days at a time without sleep.

For recreation the patient would bowl 40 or 50 games at a time, often resetting the pins if they were not all knocked down with the first ball. He had squandered his savings. Having recently become interested in girls, he joined a dating service that cost $500; he borrowed the money to pay for it.

The patient did not have a history of psychiatric illness or similar behavior. He denied using unauthorized drugs. There was no family history of manic behavior, although his mother was being treated with an antidepressant.

Upon examination at the time of his admission, the patient spoke with much difficulty at times. He stated that he was "retarded" and had trouble getting his words and ideas across. He was occasionally boisterous. He stated that a goal of hospitalization was to read better, "which would make me a better worker to help the factory, help the country, and help the world." He said he wanted to write the President a letter.

A neurological examination at the time of his admission was entirely normal. The patient was oriented and of clear consciousness. He denied hallucinations and his memory was not impaired. However, the patient's intelligence appeared to be markedly below normal; his reading ability was poor and his fund of general information low.

Initial laboratory data were normal except that the serum bromide level was 32.5 mg/100 ml (normal=less than 1.5 mg/100 ml). The toxicology laboratory verified this information. A serum bromide determination was made because the patient had a history of bizarre behavior, paranoid delusions, and an acneiform rash. His parents and employer were unable to supply information about where he might have obtained bromide. Urine toxicological screen was negative, and an EEG was normal.

During the first part of his hospital stay the patient would arise early and empty garbage cans and perform other chores on the ward although he had not been requested to do so. His speech remained pressured and

there were two episodes of marked irritability.

The patient was treated with 400 mg of chlorpromazine per day; a maximum daily dosage of 700 mg of chlorpromazine was required briefly. His verbal and motor behavior soon returned to normal levels. A serum specimen drawn 6 days later was negative for bromide. His chlorpromazine was decreased and then eliminated after he was discharged to outpatient treatment.

Two months after his discharge the patient was doing well and performing adequately at a different job in the same factory. His behavior at home was felt by his parents to be much improved. A blood specimen was negative for bromide. Six months later it was reported that the patient was continuing to do well but had had two episodes at home of irritability felt to be related to stress and his retardation. In retrospect, the patient suggested that he might have ingested an antacid containing bromide during his manic illness to relieve a recurrent upset stomach. He admitted to ingesting up to a whole bottle of the antacid daily.

DISCUSSION

Bromism is still a problem; it has been proposed that drugs containing bromide should be under prescription control or even banned from the market (5). The patient described here exhibited classical features of mania but did not show signs of bromide intoxication or delirium, although his serum bromide level was abnormally high. After his recovery the patient suggested a possible source of bromide. However, an alternative explanation is that because of his manic behavior, he medicated himself to reduce his various symptoms.

A review of case reports of patients with bromism revealed that some patients who were believed to be schizophrenic exhibited symptoms which were similar to those of mania. Such symptoms as violence, aggressiveness, agitation, delirium, talkativeness, and restlessness were used to describe patients with bromism (2). One patient who was "uninhibited and defective in concentration and memory" became "manic" after treatment to lower his bromide level and required ECT and chlorpromazine. Two recent reports (6, 7) emphasize the importance of properly diagnosing mania when one observes "schizophrenic" or other abnormal behavior. Perhaps patients previously reported as schizophrenic due to bromism were actually manic.

The importance of the case reported here is twofold. It is an important goal of clinical psychiatry to be aware of and diagnose any reversible causes of altered mental functioning. This case suggests that patients who exhibit manic behavior may benefit from an evaluation of bromide level. Establishing that bromism may be the cause of a manic episode would most likely remove the patient from the category of endogenous manic-depressive illness and the poor prognosis of a possibly recurrent disease. However, bromide ingestion may induce a manic episode in a predisposed individual, as the patient described may well be. Evaluation of additional manic patients is needed to clarify the possible relationship of mania and bromism.

Second, the implication that another monovalent ion is involved in mania may be important to research in manic-depressive illness. The possible roles of lithium have been the subject of much study (8). Recently rubidium has been suggested as important in depression (9). Hollister (10) reasoned that as lithium has the ability to replace sodium in mania, so might rubidium replace potassium in depression. Bromide has been recognized as being interchangeable with chloride (11). Although chloride is primarily an extracellular ion, its interchange with bromide may be important in mania, as the clinical data of this case suggest. Investigation of the role of the bromide ion in alterations of cellular electrolyte balance or neurotransmitter enzyme functions might be fruitful.

The clinical information from this case suggests that evaluation of manic patients should include a bromide level determination. Further research concerning the role of the bromide ion in cellular functions may result in better understanding of manic-depressive illness.

Breaking Into the Prison: Conducting a Medical Research Project

BY JEFFREY S. RUBIN

Three major tasks face the researcher in a medical experiment employing prisoners as experimental subjects. Understanding the nature of the subject, crossing the territorial boundary, and obtaining informed consent are prerequisites for the successful implementation of research in the prison and rely heavily on the personal integrity of the investigator.

THE SUCCESSFUL implementation of a medical research project employing human subjects depends heavily on an ethically sound experimental design. When the researcher uses prisoner subjects, however, he is faced with three major tasks before his program can be implemented successfully. He must understand the nature of the inmate, cross the territorial boundary, and obtain informed consent. During a period when the issue of employing human subjects has come under wide scrutiny, it seems wise for researchers who are contemplating clinical research in prisons to consider the merit of *total planning* beyond experimental design.

NATURE OF THE INMATE SUBJECT

Bach-y-Rita (1) has pointed out that the prisoner as an experimental subject demands different considerations than an outpatient population due to the nature of his environment. To protect any subject from artifactual physiological and psychological effects, the researcher must first understand the subject and his needs. In the case of the prisoner, the task of learning what motivates him is difficult for a person who is not incarcerated. Banuazizi and Movahedi (2) have stated that it is difficult for nonprisoners to understand the nature of life in a prison environment.

In the maximum-security, indeterminate-sentence facility where I gained experience with inmate research subjects, the prison society is structurally similar to its counterpart outside the prison. Prisoners react to each other based on social contacts (3). There are dictums, codes, and hierarchies among the inmates to which each is expected to adhere. The inmate population is cohesive and sets itself in juxtaposition to the administrative staff and correctional officers.

Mr. Rubin is Research Administrator, Institute of Psychiatry and Human Behavior, University of Maryland School of Medicine, 645 West Redwood St., Baltimore, Md. 21201.

With this in mind, one cannot help but notice the paradoxical nature of the inmate. Here is an individual who cannot maintain himself in outside society yet functions quite efficiently in the prison environment. The researcher should not regard the prisoner subject as an antisocial individual. In the confined society of the prison the inmate is governed by similar drives and motives for his behavior as one is in free society.

While there is a structural similarity between the two environments, the difference is one of integration. By this, I am referring to the prisoner's demonstrated lack of integration into our main society due to any number of personality problems. In his confinement he is forced to create a microsociety with certain rules in order to survive. This microsociety is a closed one, and acceptance of outsiders is rare. The researcher, as an outsider to the microsociety within the prison, must first realize that it indeed exists and then cross the barrier in his search for subjects.

CROSSING THE TERRITORIAL BARRIER

At issue here is the mistrust that one group of people feels toward another group, whom they view as outsiders. As obvious and natural as this attitude may seem on the surface, a researcher can mistakenly assume that trust implicitly exists before the stage has been set. In his eagerness to obtain volunteers for his project, the researcher may inadvertently destroy the formation of a trusting relationship by an overzealously cooperative attitude.

I have found that many prisoners, before consenting to participate in a medical experiment, create their own type of experiment on the researcher to test his honesty and integrity, qualities that are valued highly in the microsociety. One such "test" I have frequently encountered is a mock intimidation by one or more inmates. The intimidation occasionally took the form of verbal attack against all prison research; in this case, the inmates were testing the investigator's personal convictions concerning his work. On other occasions the intimidation took the form of a verbal attack against the outside society; in this case, the inmates were testing the investigator's attitudes about criminals.

From this discussion one can see that these prisoners are clever individuals who realize that incensing a person through intimidation effectively precludes carefully planned approaches. I discovered that crossing the territorial boundary and gaining acceptance for my-

self and my research did not hinge on patronization or avoidance, but rather on stating personal feelings openly and honestly. The bridge is honest acceptance for who the prisoner is, unclouded by condemnation or condonation.

Once the researcher is integrated into the prison society, the last task he must face in implementing his project is obtaining informed consent.

INFORMED CONSENT

In recent years the issue of informed consent has come under public scrutiny, together with prison research in general. There has been much controversy over what constitutes informed consent as well as the degree to which a researcher can inform his subject before he invalidates his experiment.

Some clinical investigators (4) have articulated the dilemma facing researchers in trying to obtain informed consent by stating their agreement that in prison settings it may truly be impossible to obtain a totally free consent from a prisoner; however, is it not denying them their rights to refuse to allow them the opportunity to participate in research?

Arguments by both proponents and opponents of prison research tend to center on the issue of informed consent. I feel that a rigorous informed consent, mediated with a necessity to conduct a valid experiment, is an ethically sound research practice. The guidelines set forth by the Department of Health, Education, and Welfare (5, 6) are not meant to halt prison research but to ensure keen awareness of the need to protect all human subjects in medical research.

Although there are many types of experimental designs open to the clinical investigator, each involves different methodologies and necessitates different procedures. Generally, in the prison setting there is a common set of criteria that must be met in obtaining the informed consent of prisoners. In effect, the way in which the researcher meets the strict demands of informed consent mirrors how he truly views the subjects of his experiment.

The primary phase of obtaining informed consent is based on the investigator's careful and conscious desire to make his subject aware of the nature of the research and its potential hazards, both known and unknown. At the risk of perhaps frightening subjects from participating, the investigator owes the subject complete honesty regarding these issues. For a variety of reasons the prisoner may be more likely to volunteer out of covert pressure than his own willingness (1). If anything, a complete explanation of all the hazards may offset some of the pressure to participate, including the financial compensation, which is difficult for the inmate to resist.

Also imperative in obtaining consent is an enumeration of all the procedures to be performed, including a comprehensible explanation of medical procedures. I have found it a good idea to ask the inmate to restate what he understood was expected of him in order to ascertain whether he fully comprehended the given explanation.

In addition, it is advisable to inform the inmate both orally and in writing that subjects are in no way being intentionally coerced into participation—that it is strictly on a volunteer basis. The prisoner must be made to feel totally nonthreatened if he signs a consent form. Even if he is not led to believe that participation may influence his release from the prison, he may assume it. A good method for offsetting such unwarranted beliefs is stating and adhering to the principle of total confidentiality of all information gathered, including a prospective subject's refusal to participate.

I have found that a majority of prisoners believe that signing a consent form guarantees the prisoner's participation and releases the investigator from medical and legal responsibility for the care of subjects. I therefore feel it is wise to state in writing that in no way does an inmate's signature on the consent form indicate that a contract has been signed to guarantee participation or to release the investigator from any responsibility.

After the prisoner subject is made aware of this last point, the investigator can then explain the possible benefits of the research project to the prisoner, including any financial compensation. It is imperative that the researcher make a conscious effort not to make the benefits too attractive; otherwise, he may jeopardize the concept of "free" informed consent. Due to the nature of the prisoner subject, he may view as benefits of a particular research study those aspects which were not intended as a benefit, such as a chance to get "high," a break in routine, or advance knowledge of certain psychological tests.

Finally, in the consent interview with the prisoner and all through the program, the investigator should encourage questions. Frequently a prisoner will ask candid questions about experimental design that, if answered, may invalidate the results. When this happens it is best to answer the question as completely and clearly as possible and simply state that certain information cannot be disclosed to the subject until the experiment has been completed. An example of this would be a prisoner in a double-blind study asking whether he was receiving placebo or active medication.

CONCLUSIONS

A common thread emerges in accomplishing the tasks of understanding the prisoner, crossing the barriers between his society and the researcher's, and obtaining his informed consent. The personal honesty and integrity of the researcher are precursors to success. The prisoner is as much interested in the person or individuals who organize and administrate a medical research project as he is in the project itself.

Workshop on Writing for Scientific Journals

The 1976 annual meeting of the American Psychiatric Association will feature the third annual workshop on writing for scientific journals, to be held from 9 a.m. to 5 p.m. on Sunday, May 9 (the day before the annual meeting begins). The workshop, cosponsored by APA and the American Medical Writers Association (AMWA), will offer practical information and instruction on four subjects: common writing faults, organizing psychiatric reports, getting your words on paper, and submitting a manuscript. Work assignments, which will be sent to registrants before the meeting, will form the basis for initial discussions during the workshop sessions. The course will begin with brief introductory lectures by the AMWA faculty, who include Charles G. Roland, M.D., chairman of the Department of Biomedical Communications, the Mayo Foundation, and Ms. Barbara G. Cox, medical writer, Instructional Development Section, the Mayo Foundation. A third member of the AMWA faculty will also participate in the meeting. Following the lectures there will be small-group discussions on the four basic subjects. The workshop will conclude with a panel discussion in which participants will have the opportunity to question the editors of several psychiatric journals.

Registration is limited to 40 participants. All applications for participation must be received by April 1; the registration fee is $65. For further information on registration write to Charles G. Roland, M.D., Department of Biomedical Communications, the Mayo Foundation, Rochester, Minn. 55901.

LETTERS TO THE EDITOR

Treatment of Accidental Naltrexone-Induced Withdrawal

SIR: EN-1639A (naltrexone) is a narcotic antagonist used for the treatment of heroin dependence. Naltrexone must be preceded by detoxification: patients should be opiate-free for at least a week before treatment is begun (1). Three cases of accidental ingestion of naltrexone by individuals dependent on opiates were reported by Tornabene (2). The treatment of the withdrawal syndrome consisted primarily of replacement of fluids lost by vomiting and diarrhea. One of the patients received 10 mg of morphine and low doses of methadone; these doses were ineffective.

We wish to report a similar case that was treated successfully with very large doses of hydromorphone (Dilaudid). The patient was a 28-year-old male ex-addict who had been maintained on 100 mg of methadone a day for 2 years. He had stopped using heroin but had started using alcohol and was admitted to an inpatient unit for alcohol detoxification. At 10:00 a.m. on the fourth day he was given by mistake 100 mg of naltrexone orally instead of his 100-mg dose of methadone.

At 10:10 a.m., the patient complained of chills and abdominal and muscular pain. He had generalized pilo-erection, extremely dilated pupils, and was also agitated. Subcutaneous administration of 4 mg of hydromorphone was without effect. At 10:17 a.m., he was given 4 mg of hydromorphone intravenously, after which he started vomiting and became extremely agitated. His chills and pains worsened and his pupils remained unchanged. At 10:22 a.m., he was given 10 mg of hydromorphone intravenously. His pupils showed very slight constriction, but he remained extremely agitated and ill. A further 10-mg intravenous dose of hydromorphone was given at 10:27 a.m.; his restlessness abated slightly, the vomiting stopped, and his pupils returned to normal size. Pilo-erection and chills persisted. At 11:10 a.m., the patient felt better but still complained of abdominal and muscular pain and was yawning. At 11:30 a.m., 20 mg of hydromorphone was administered intravenously. After this injection, the patient was still restless, yawning, and generally uncomfortable. Another 20 mg of hydromorphone was given, and at 11:45 a.m., the patient felt considerably better, but he was still somewhat restless and uncomfortable. He was given 10 mg of hydromorphone intravenously and 100 mg of methadone orally.

He felt well until 6:00 p.m., at which time he started complaining of chills. A total of 175 mg of methadone was given orally in divided doses over a period of 4 hours. At 11:00 p.m., he again complained of withdrawal symptoms and was given 8 mg of hydromorphone subcutaneously and 75 mg of methadone. He slept little that night, complaining of discomfort.

The next morning he felt weak and complained of headaches. He received a total of 200 mg of methadone in 3 doses on that day. On the third day, he was back on his regular dose of 100 mg of methadone without symptoms.

To summarize, an acute withdrawal syndrome was precipitated when naltrexone was given by mistake to a patient who was dependent on methadone. The treatment required a very large dose of hydromorphone—78 mg in the first 2 hours. Withdrawal signs and symptoms were used as guides for determining hydromorphone dosage.

Certification for Foreign Medical Graduates

SIR: As a member-in-training of the American Psychiatric Association, I would like to address APA members on the difficulty I am experiencing in becoming a full member of the association and seek their support for other individuals in situations like mine. I came to this country on an exchange visit. After I completed my residency in 1972, I suffered an intense conflict over the decision of staying here or going back to my country as a noncertified psychiatrist. After much turmoil and expert help, I went home in 1972. It was there that I realized that until I pass the American Board of Psychiatry and Neurology (ABPN) examination, I will merely be cheap labor both in the United States and my home country. I came back to the United States just to do that; however, the ABPN representative said that although my training is acceptable, I must have an unrestricted license in one of the states. I consider this an unnecessary requirement; I feel that successful completion of the ECFMG and licensing from my home country should suffice. Unless I complete this "initiation ceremony," I will remain a member-in-training in this country; I will be judged in need of further training in Canada and will be cheap psychiatric labor in poorer nations.

I would appreciate responses to this letter from my colleagues in the United States and from other foreign medical graduates (FMGs) in order to prepare a paper on this subject. (My definition of FMG is anyone who graduated from medical school outside the United States and who intends to stay in this country—this includes Canadians and U.S. citizens who have graduated from medical schools in other countries.) I would like to hear anything on the general topic of the situation of FMGs in American psychiatry from those

FMGs who plan to become a part of American psychiatry and American life. My goal could be better accomplished if I could compare this group with those FMGs who definitely plan to return to their home countries, but this variable is not predictable unless one has the resources to contact those who have actually followed through on this decision. I am trying to get such a comparison group from at least one country.

I will welcome responses at the address given below until July 1976.

Parens Patriae and Psychiatry

SIR: It is remarkable to watch psychiatry attempting to plug the holes in the badly leaking vessel traditionally thought to contain the rationale for its *parens patriae* powers. The recent opinion "Is Dangerousness an Issue for Physicians in Emergency Commitment?" by Michael Alfred Peszke, M.D., and the comment by Alan A. Stone, M.D. (August 1975 issue), are examples of our apparent anxiety regarding our future as a profession without the power to force ourselves on unwilling patients.

Dr. Peszke correctly makes the point that when a psychiatrist commits a patient for "dangerousness," he is acting as an agent of the state. He then asks us to believe that if we force treatment on a patient using some other justification, we have somehow become the patient's agent. His reliance on our position as physicians to justify imposing intervention "only when there are sound and documented medical reasons" is particularly ironic because no physicians other than psychiatrists have asked for or been granted power to impose treatment.

Dr. Peszke would also have us equate lack of forced treatment with no treatment—we would be abandoning those seeking or accepting help if we no longer forced anything on those who did not seek or accept help. Dr. Stone does similar insult to the language by warning us that by relying on dangerousness as a commitment criterion, nondangerous individuals "will no longer have access to involuntary mental health care."

While properly decrying dangerousness as a valid reason for involuntary treatment, Dr. Peszke believes that "The physician can make a judgment that the severity of mental illness has impaired a patient's competence to make an informed decision as to the risks involved in not obtaining treatment." This, we are told, "returns the physician to his historical role as an agent for the patient's welfare rather than an agent of society." He gives no reason—and I see no reason—to believe that a return to an "in need of treatment" standard would do anything but make the situation worse.

Dr. Stone also suggested that we assess whether "a reasonable man in this situation [would] give up this much freedom for this much treatment." This standard is supposed to keep emergency commitment facilities from becoming jails and treatment from being preventive detention.

Could it be that more people will inevitably be harmed rather than helped by our forced intervention? A recent example is the young man who, upon losing his court battle to avoid conservatorial incarceration at the Napa State Hospital, leaped to his death from the Sacramento Medical Center. This should remind us of the quote from our Viet Nam experience: "We had to destroy the town in order to save it."

Might it not be wiser to recognize that not only dangerousness but all of the commitment criteria that we are using to justify and enforce preventive detention in facilities that are as much like jails as hospitals are lacking in scientific, clinical, and social merit? We can only become the true agents of our patients rather than of the state by renouncing all state power to force anything on anyone.

LEE COLEMAN, M.D.
Berkeley, Calif.

Dr. Peszke Replies

SIR: The fundamental issue here is whether our society will continue to accept as expedient and moral public policy the premise that severe forms of mental illness limit autonomy. To accept such a principle is certainly not necessarily to have clear-cut criteria for its implementation. I would in no way argue that the quality of care in many state institutions in this country is what a "modern" society has the right to expect.

I cannot agree with Dr. Coleman's statement that psychiatrists are the only physicians who have been granted or asked for the power to impose treatment on involuntary patients. Historically, this mandate has arisen from society and has been delegated to physicians. Only in the last 50 years has it become a psychiatric issue. In most countries, licensed physicians are mandated to commit mentally ill patients for emergency treatment and/or observation. Furthermore, most primary care physicians are continually confronted with patients who are unconscious or for other reasons unable to give informed consent. In many of these cases, the procedures that are performed are far more dramatic and heroic—and the results more untoward—than the average involuntary treatment in a mental institution.

Dr. Coleman poses the traditional question of whether more people will be harmed than helped by our forced interventions. Surely, the issue is what people and what kinds of forced intervention. We would not consider it a good practice to automatically do a tracheostomy on every patient who arrives in the emergency room following an accident, and yet such interventions are at times desirable and, in fact, lifesaving. There has to be some judgment about the harm to the patient that will result without treatment as opposed to the likelihood of benefit.

Dr. Coleman obviously misunderstood one of my arguments. I prefer the voluntary route for every patient, and I only wish that our institutions were able to provide quality care to everyone who wishes to be treated.

I do not relish the decision-making process when I am confronted with a patient who is psychotic, who refuses treatment, and whose welfare is jeopardized by his illness—particularly in cases where I know from experience that appropriate and available treatment would be helpful. I know that many psychiatrists share my reluctance in such difficult situations. I have on many occasions urged that the power to commit should be confined to specially licensed, forensically trained public health psychiatrists, working with appropriately trained attorneys. This system would provide emergency care while acting as a system of checks and balances in the clinical and administrative decision-making process.

The practice of involuntary treatment exists in most so-

cieties. It is a cross-cultural, historically legally sanctioned and philosophically acceptable approach to those people whom society considers to be at risk and to lack competence or autonomy. Society can change these ground rules. But unless we, as a profession, think that people who are seriously ill are only playing a role, then we owe it to society to show our concern, present the risks and options, and leave it to society to determine policy. It is important that we not allow society to make rules and regulations that are inimical to our professional concerns and incompatible with our expertise.

MICHAEL A. PESZKE, M.D.
Farmington, Conn.

Convulsions Following Disulfiram Treatment

SIR: We wish to report the occurrence of grand mal seizures in a patient who was taking disulfiram (Antabuse) and was abstinent. To our knowledge there has been only one previous report of such a case (1).

Our patient, a 50-year-old chronic alcoholic female, had been taking disulfiram for 6 months and had no history of neurologic seizure disorder. While she was taking 250 mg of disulfiram by mouth daily and was totally abstinent (as confirmed by her family and our observations in the hospital), she had five documented grand mal seizures. They occurred in the context of a clinical delirium that had apparently developed gradually over a 5- to 6-week period. The seizures cleared rapidly with discontinuation of the disulfiram and institution of phenobarbital and diphenylhydantoin therapy. No abnormalities were found on physical examination (except for hepatolienomegaly, thought to reflect her prior alcoholism), routine laboratory evaluations, neurologic examination, lumbar puncture, brain scan, or skull films. An initial EEG showed fast spikey background activity interpreted as being suggestive of a drug effect. A subsequent EEG, done 3 weeks after disulfiram had been discontinued, was normal and corresponded to gradual clearing of her delirium. The anticonvulsant medications were discontinued 3 weeks after admission and she has remained seizure-free, cognitively clear, and clinically well for the 6 months since her discharge.

When seizures occur in a patient taking disulfiram, they are thought to reflect an alcohol-disulfiram interaction. Since the variety of clinical situations that can lead to seizures in alcoholics is very broad, and appropriate and definitive treatment is largely dependent on an accurate diagnosis, the possibility of seizures as a direct side effect of disulfiram—even in the absence of a challenge by alcohol and especially if they occur in the context of a clinical delirium—must be considered in the differential diagnosis. Appropriate treatment is discontinuation of disulfiram and temporary institution of anticonvulsant therapy for the period of time during which the drug is being eliminated from the system.

TREVOR R.P. PRICE, M.D.
PETER M. SILBERFARB, M.D.
Hanover, N.H.

Diabetes Insipidus and Obsessional Neurosis

SIR: The syndrome of "Acute Psychosis, Increased Water Ingestion, and Inappropriate Antidiuretic Hormone Secretion" reported by Murray A. Raskind, M.D., and associates (September 1975 issue) is of great interest. I have been following the association of psychiatric disturbance with diabetes insipidus since 1952, and in 1956 I described a syndrome of diabetes insipidus and obsessional neurosis, reporting nine cases (1). Three had been under my care (2), four had been described by other authors (3–6), and two were patients I interviewed in 1955.

The third case in my series was a woman who had been admitted to several hospitals where her obsessional features were never noticed. The patient admitted she had never told any physician about her obsessional compulsions and ruminations and that when asked specifically at one hospital, she had denied them altogether, although they had been plaguing her for years. In view of my experience that these obsessional features almost invariably go undiagnosed, I think it fair to presume that obsessional features were present in the cases presented by Dr. Raskind and associates, since they were so similar to two of my patients in many respects.

I suggest that obsessional neurosis and evidence of hypothalamic disturbance should be sought in all cases of diabetes insipidus, as I am confident this syndrome is more common than is supposed. Identification of further cases and adequate examination may contribute to our knowledge of the anatomy and physiology of appetite, thirst, and compulsion.

It may be that this syndrome could also give us a glimpse of the source or site of the generation of the "energy" underlying cathexis. Just as the syndrome of bitemporal hemianopia and diabetes insipidus suggested a single lesion in the region of the optic chiasma to Kruse in 1894 (7), which led to the investigation and further understanding of the neurohypophysis, it may be that antidiuretic hormone (ADH) or chemically similar compounds will be found to attentuate or control compulsive drives more specifically than the psychotropic drugs now available.

There is some doubt surrounding presently held concepts of the actions of ADH, since injection of aqueous vasopressin (Pitressin) reduces thirst dramatically in some patients before it could have had time to modify fluid and electrolyte balance by even 1%.

One of my patients lost her compulsions when her thirst was controlled by vasopressin. Since there is a subjective feeling of compulsion in both thirst and obsessional neurosis, there is clearly a wide area for speculation and investigation in the small area of the brain mentioned by Dr. Raskind and associates.

It was disappointing that six patients with severe obsessional neurosis without diabetes insipidus did not respond to the administration of small doses of vasopressin.

RUSSELL BARTON, M.D.
Rochester, N.Y.

Lithium and Affective Disorders Associated with Organic Brain Impairment

SIR: The recent articles by Alan H. Rosenbaum, M.D., and Maurice J. Barry, Jr., M.D., regarding "Positive Therapeutic Response to Lithium in Hypomania Secondary to Organic Brain Syndrome" (October 1975) encouraged me to report the following case. I think this patient is unique in several ways and although lithium would generally be used with reluctance in patients with organicity, she seems to have responded to this treatment well.

The patient is a 61-year-old nun trained as a practical nurse. She was admitted in December 1973 for the fourth time to St. Louis State Hospital Complex, St. Louis, Mo., for continuing illness with main symptoms of confusion and depression.

Her psychiatric illness started in 1937, with a short episode of depression that did not require hospitalization. In 1939, the patient was hospitalized for depression with "somatic fixation, withdrawal, and inability to take care of her personal appearance." She had several short hospitalizations for essentially similar complaints in the next 2 years. In 1941, the possibility of multiple sclerosis was first considered. The patient had undergone repeated episodes of weakness of legs with incontinence and had subsequent complete disappearance of neurologic symptoms and signs.

The patient continued to suffer from frequent periods of depression until 1961. Electroconvulsive therapy (ECT) was used a number of times with apparent favorable results. In 1963 she was rehospitalized for extreme exhaustion, nystagmus, paraesthesia, and hyperreflexia on the left side with extensor plantar. Her medical management included intravenous histamine and steroids. However, the patient was noted to be quite depressed, and antidepressants were not effective. A course of ECT resulted in the development of talkative, argumentative, and belligerent behavior that was considered hypomanic and treated with chlorpromazine.

In 1964 the patient was readmitted for complaints of depression and anxiety. There was little improvement from treatment, and in 1967 long-term institutional care was finally considered. The patient was characterized as being "continuously psychotic, depressed, withdrawn, and careless of her personal hygiene and having a clouded sensorium." In 1968, she was first admitted to St. Louis State Hospital. On admission she was covered with feces from head to foot. She had a neurogenic bladder and a urinary tract infection. In 1969, she was noted to have mild dysarthria, scanning speech, positive Romberg's sign, unsteady gait, poor coordination with cogwheel rigidity, fine resting tremors, weakness of muscles, and diminished deep reflexes.

In 1970, the patient was reported to have become withdrawn, confused, and depressed. She also had frequent slips and falls and was generally clumsy. She had further admissions in 1971, 1972, and 1973 essentially for depressed affect, withdrawal, psychomotor retardation, urinary incontinence, inability to care for herself, refusal to eat, and crying spells. In her admissions to this hospital from 1968 until 1973, the patient was treated symptomatically with various phenothiazines and antidepressants. Her recurrent chest and urinary tract infections were treated with antibiotics. She was given small doses of anticholinergic drugs for her Parkinsonism.

The patient's complete blood count revealed mild anemia (12 g/100ml), sedimentation rate of 28 mm/hour, serum folic acid 2.4 g/ml (normal = 2.5 to 12). The patient's serum B_{12}, thyroid function test, urinalysis, and glucose tolerance test were within normal limits. Venereal disease and tuberculin tests were negative. X ray of chest, skull, and cervical spine were essentially within normal limits. Cerebrospinal fluid examination revealed mild elevation of proteins. EEG showed generalized dysfunction. EKG, brain scan, and right carotid angiogram were within normal limits. Psychological tests showed nonlateralizing organic brain impairment.

In view of the patient's history of repeated episodes of neurologic dysfunction with resolution over a period of time, she was considered to have multiple sclerosis. She seemed also to have recurrent affective illness, either associated with or uncovered by multiple sclerosis. As she had no cardiac, renal, or hepatic contraindication for lithium therapy, she was put on this treatment and has now been on it for some 20 months without complications and is doing quite well. It would appear that some patients with organic brain impairment and recurrent affective disorder might benefit from lithium.

St. Louis, Mo.

Correction

There is an error in the article "A Hierarchy of Drug Use in Adolescence: Behavioral and Attitudinal Correlates of Substantial Drug Use," by Beatrix A. Hamburg, M.D., Helena C. Kraemer, Ph.D., and William Jahnke (November 1975 issue). In figure 1, page 1159, the authors inadvertently interchanged the labels of the curves representing hard liquor and tobacco usage.

BOOK REVIEWS

Why Survive? Being Old in America, *by Robert N. Butler, M.D. New York, N.Y., Harper & Row, 1975, 482 pp., $15.00.*

This is a sad and disturbing book, yet it is timely and of real importance. It is an excellent work that is difficult to review because one would like to quote extensively from it. Written by a man who obviously loves old people and who champions their cause, the book awakens deep emotional reactions; Dr. Butler demonstrates that in many instances old age in these United States is indeed a tragedy. He recognizes that some old folks are sick and that some are well, that some are rich and many more are poor, and he lifts a curtain so that we may see a side of life that is usually hidden from us or that we have not cared to see. He reports that at least 30% of the nation's more than 20 million elderly live in substandard housing and that over 10 million of them live on less than $75 a week—$10 a day.

Just as racism and sexism are abroad in the land, so too, says Dr. Butler, is another form of bigotry that he calls "ageism"—a widespread prejudice against the elderly in government, industry, housing, and, saddest of all for us, in medical practice, including psychiatry.

The myth of aging, the idea of inflexibility, unproductivity, and senility as inevitable accompaniments of age, is unfortunate; there are great differences to be found among the older age groups. Old women fare worse than old men, for instance. Many elderly people who suffer from reversible medical conditions are labeled senile and packed off to institutions. Many respond to the prejudice: some act senile, others try to conceal their age, and some attempt to appear young.

Every day more than 1,000 people pass over that artificial barrier which marks old age—65 years. This age group now comprises over 10% of the population of the United States; in 1903 this figure was 3%. Negative attitudes toward this age group range from pity to direct hostility, from infantilization to neglect or avoidance. Old age, the author says, has become an absurdity.

In the chapter titled "How To Grow Old and Poor in an Affluent Society," Dr. Butler notes that single women, widows, and members of minority groups fare worst of all of the elderly groups economically. The minority groups are in double jeopardy. We hear very little about these people because they do not court attention. They escape notice by staying in their homes or in their lonely rooms, locked in by timidity, illness, disability, lack of money, poor transportation, or fear of crime. In low-cost restaurants (if they can be found) they linger over a cup of coffee or a roll, often to the distress of the proprietor and the other customers. Their alternatives are hot dog stands or a hot plate in a furnished room.

Dr. Butler discusses the difficulties encountered in trying to collect pensions and the disheartening hunt for a place to live. He describes how old people wait endlessly for services essential for survival and the capacity to live independently. He observes that many of the elderly cannot afford proper medical care and that doctors and other health care personnel have not been trained to deal properly with them.

Direct as well as general prejudices against the elderly exist because they require more time from physicians and, often, are unlovely as individuals. Under difficult circumstances the elderly may at times become disoriented and demonstrate fluctuating awareness. This may be caused by congestive heart failure, head trauma, alcohol intake, dehydration, or cerebral vascular accidents. Given proper treatment, their chances of recovery are high. The danger, of course, is that they are often regarded as only senile or arteriosclerotic and sent to a nursing home. Once that magic word "senile" is uttered, the cause is regarded as lost.

Dr. Butler explores in depth the degradation that old patients experience in hospitals: they are not regarded as desirable patients. They get what he calls the "emergency room hustle" and "the transfer": "shut the door and wait." The final indignity is to isolate them when they are dying: one of the greatest fears of the elderly is that of dying alone.

Psychiatry does not do any better than general medicine in taking care of the elderly, although research reports indicate that older patients can benefit from mental health care. Dr. Butler points out that as many as 75% of patients over 65 in private hospitals can return to their own homes in two months. The difficulty, of course, is that most of the elderly cannot afford the level of care provided in private hospitals. Butler also speaks of the "Yavis syndrome," which is the therapist's interest in patients who are "young, attractive, verbal, intelligent, and successful." Therapists who do not work in public hospitals or clinics see patients from only a narrow band of the American population.

The book also deals with nursing homes, the victimization of the elderly, and the crimes of violence and frauds that are perpetrated against them. Politicians make promises to the elderly to pacify them, but in the end they neglect them. It all makes for a sorry story of man's inhumanity to man.

The final chapter, "Growing Old Absurd," ends with the following statement:

> After one has lived a life of meaning, death may lose much of its terror. For what we fear most is not really death but a meaningless and absurd life. I believe most human beings can accept the basic fairness of each generation's taking its turn on the face of the planet if they are not cheated out of the full measure of their own turn. The tragedy of old age in America is that we have made absurdity all but inevitable. We have cheated ourselves. But we still have the possibility of making life a work of art.

Thus the author examines the subject of aging in all of its complexities. He becomes personally involved with his subject, and his deep feelings are evident. The book is a labor of love. One leaves it depressed, but to understand the overall problems of the aged one of necessity has to read it.

F.J.B.

The Alternate Services: Their Role in Mental Health, *by Raymond M. Glasscote, M.A., James B. Raybin, M.D., Clifford B. Reifler, M.D., and Andrew W. Kane, Ph.D. Washington, D.C., Joint Information Service of the American Psychiatric Association and the National Association for Mental Health, 1975, 329 pp., $8.00.*

In a style that is now familiar, Glasscote and his collaborators report a study of a small but representative group of service delivery systems that typify a larger area of service systems in the mental health field. In this book 14 programs of recent vintage were studied through questionnaires and site visits. The findings have been summarized in separate chapters for each of the 14 programs. The service units range from hotlines and walk-in counseling centers to runaway houses, free clinics, and a residential center using the encounter techniques of therapeutic communities.

The authors' descriptions of these alternate services are well written, vivid, and as comprehensive as the various services would permit. In their words, "Alternate services are more or less targeted to teenagers and young adults whereas in traditional helping services, both medical and psychiatric, there has been in many places a distinct lack of services for this age group." They recognize that many of the alternative services had their origins in the drug crisis, epidemic, and panic of the past decade. Moreover, they note that these alternate services have increasingly shifted their focus from drug problems to the problems in living faced by juvenile offenders and by the depressed, lonely, or alienated members of society who are not drug users. The authors note, "It seems likely for the foreseeable future that our society will produce an ample supply of clients for the alternate services."

Perhaps one of the advantages of this book lies in the fact that it represents an interesting chronicle of the origins, struggles for survival, use of volunteers, and, in some cases, the demise of alternate services, which have been so enthusiastically developed throughout the United States in the past few years. It appears that the authors have been extremely fair in their approach; to the casual reader it might seem that they were lending their full support to these varied treatment programs. It seems possible that an uncritical lay reader might assume that alternate services show the way for the future.

For example, in the preface to this book Senator Birch E. Bayh, Jr., chairman of the Senate Subcommittee to Investigate Juvenile Delinquency, views this book as an inspiration, as an affirmation of the American tradition of volunteering to help one's fellows. Senator Bayh also states that the book documents "that as a nation we are able to respond quickly and appropriately to newly recognized and emerging needs." Senator Bayh was impressed that "the unit cost of services has been correspondingly low" in the alternate services at a time when "the cost of helping services seems to escalate at least as rapidly as the cost of everything else." He is encouraged to read that free clinics and telephone counseling services are still growing in number. He is "reassured to learn that originally highly specialized services have recognized the need to learn how to respond skillfully to the great variety of troubles and stresses that are part of growing up."

However, an important attitude of the authors toward the alternate services is best revealed in the following statements about various programs:

> As with other programs, their efficacy in bringing about lasting and desirable change in behavior is unknown. . . . Unfortunately, not one of the 14 programs could furnish data that would allow a combined compilation of the clientele. . . . We cannot even comment on the effectiveness or suitability of the response that these 14 alternative services made since none of them have follow-up data. . . .
>
> If the center has its distinctive qualities, it has one that it shares with everyone else. It has no good data concerning the effectiveness of the services it provides. . . .
>
> If outcome data for this interesting and rich program should ever become available they will result from efforts that are, at present, not even under consideration. . . .
>
> It would be astonishing if this program had any systematic information about the young people who leave it. And it does not. . . .
>
> The data available . . . are not exactly a researcher's paradise.

Inasmuch as more enthusiasm than research interest has surrounded the development of the alternate services, and inasmuch as efficacy data for these services are largely nonexistent at the present time, one might take the attitude that many of these services represent a special form of human research. It would be surprising to me if the guidelines for human research of the U.S. Department of Health, Education, and Welfare (HEW) were familiar, in any way, to most of the services described by Glasscote and his colleagues.

Because several of these services have received federal or state grants, one could ask what business the federal and state governments have in providing treatment funds for services that have no documented effectiveness. The answer to this question could probably be found in the therapeutic optimism of some funding agencies. Perhaps even more of the answer could be found in an amorphous HEW, in which agency heads responsible for dispersing treatment dollars may not be familiar with human research or their own agency's guidelines for the conduct of human research.

Some readers with a more traditional outlook might wonder what happened to demonstration research. It remains clear that a new and innovative service system that is unstudied contains the possibility of providing services that are not effective or are, in fact, destructive. This note of concern can be read between the lines in this book. Nevertheless, the genuine concern of volunteers for helping those who are in trouble represents a source of time, money, and manpower that is invaluable in the field of human services. The enthusiastic supporters of alternate services should recognize that a prolonged failure to study the effectiveness and suitability of these services may eventually be the most destructive course that can be followed in regard to the long-term survival of these services.

No reader of this book will miss the desperate financial plight and struggle for survival that has been common to the several services described. It seems clear that solid, respectable efficacy data could be most helpful in ensuring a less troubled existence for those selected services which should survive on the grounds of their excellence and high quality.

For those interested in a further pondering of the sociologic mysteries surrounding American youth over the past decade this book will provide fascinating background material. For those who wonder about the quality and acceptability of care in America's large medical institutions this book provides information for further speculation.

Finally, for those who subscribe to the concept of *primum non nocere*, this book will raise a lingering doubt that the alternate services have been overbalanced with therapeutic optimism and antiscience.

VERNON D. PATCH, M.D.
Boston, Mass.

Supportive Care: Theory and Technique, 2nd ed., *by Werner M. Mendel. Los Angeles, Calif., Mara Books, 1975, 237 pp., $12.00.*

Dr. Mendel provides us with a clear, vivid description of how he cares for chronic mentally ill patients, especially chronic schizophrenic patients. His book is concrete, practical, richly illustrated with clinical examples, free of jargon, and easy to follow. It will also be easy for experienced therapists to identify just where they do or do not agree with him and to trace the consequences of his basic philosophy of treatment throughout his technical advice.

"Supportive care" is defined as "that management which relieves suffering, prevents complications, and allows the patient to function at or near his capacity." It is sharply differentiated from "expressive" treatment, which is seen as contradictory and contraindicated for chronic patients: "Expressive techniques are contraindicated with the psychotic patient or for the patient classified as borderline psychotic." This sharp polarization of the two different treatments rather than a conceptualization of them as two different themes found in varying proportion in every psychotherapy may seem unwise to some readers. However, it is pedagogically effective, and it is associated with Dr. Mendel's view of chronic mental illness (essentially chronic schizophrenia) as a disability rather than a disease.

Dr. Mendel's treatment is a psychotherapy aimed at helping patients adjust and adapt to their disability; it holds no expectation of altering any basic underlying process. He is particularly effective in discussing therapeutic problems encountered in treating the chronically disabled, such as transference and countertransference issues, dependency and trust, the emerging "real" relationship with the therapist, change of therapists, and institutional transference. In keeping with his model, there is no discussion of therapeutic maneuvers designed to alter the primary deficits themselves.

Dr. Mendel's method is also based on his somewhat idiosyncratic view of schizophrenia:

> There are three primary defects which are the basis of the chronic schizophrenic illness and which are seen in such schizophrenic existences. These are (1) *the failure of historicity*, (2) *expensive and ineffective management of anxiety*, and (3) *disastrously painful and unsuccessful interpersonal transactions*. All other signs and symptoms of schizophrenia are secondary to these three defects.

By "historicity" (an unfortunate term and concept, in my opinion), he means the "lived history which the person brings to the task of conducting his life and which influences his perception of himself and others, his behavior, his emotional response, and his attitudes." This view of schizophrenia is not elaborated, tested against other views, or defended in the book, but it is always implicit in the technical recommendations. I suspect that it stems not so much from a theoretical refinement of prevailing views as from an extrapolation backward from the clinical maneuvers that the author has found useful. As such, like the book as a whole, it is heuristically valuable but scientifically unsatisfying. In a way, it is an antidote to the current popular discussion of expressive dynamic psychotherapies for schizophrenic and borderline patients, but a true synthesis of these two approaches is still wanting.

Although there is much with which to agree or disagree in this book, there is only one point on which I found the author's view unreasonably prejudiced—the role of the psychiatric hospital. He has apparently had some bad experiences with hospitals and seems to have generalized from them. In one passage he discusses the therapist's expectations as self-fulfilling prophecies; perhaps that complicates his use of hospitals. His views speak for themselves: in discussing the suicidal patient, "It is always best for the patient not to be hospitalized," and in discussing the patient's family, "Even a disorganized family, with proper management, is more therapeutic than a psychiatric hospital." The latter statement is sometimes true, but it hardly represents an ironclad principle.

The book has many lists and many rules. Not always theoretically satisfying, they more than make up for this by their clarity and pedagogic value. One suspects that we are being educated supportively. By the constant gentle push toward pragmatic action in the real world, we get a taste of the experience of a patient receiving supportive care. For those who profit from supportive education, or for those who are free to stand back from it, the approach is excellent. We learn that all psychotherapy can be resolved in 5 essential steps, that there are 16 indications for hospitalization, that there are 4 antitherapeutic factors always part of hospitalization, that appointments must never be canceled (to me a dangerous rule—it will inevitably get broken and, if treated as an absolute, the consequences will be magnified), and finally, that "it can be stated categorically that if a member of a hospital staff is struck by a patient he has erred in the performance of his therapeutic task." This last statement is certainly not true with patients who have brain syndromes.

The book includes a chapter on medication by Robert Allen, M.D., and one on ECT by Max Pepernik, M.D. The latter is usually optimistic about results, going far beyond the usually accepted view of the role of ECT in chronic schizophrenia. The bibliography, which is nicely annotated, essentially stops in 1968 (about the time of the first edition).

This is a valuable book for those who work with the chronically mentally ill. It will be most useful for training those who work within the author's frame of reference and for broadening the perspectives of experienced therapists with other points of view. It is not a general text and does not pretend to be one. The author's skill and experience as both therapist and teacher are clear, and his willingness to describe what he does in detail is most commendable.

ROBERT MICHELS, M.D.
New York, N.Y.

The Residential Psychiatric Treatment of Children, *edited by Philip Barker, M.B., D.P.M., D.C.H. New York, N.Y., Halsted Press (John Wiley & Sons), 1974, 346 pp., $22.50.*

This is a fine presentation of the current state of the art and practice of the field of residential psychiatric treatment of children in Great Britain. An extra dividend for the American reader is a review of the accomplishments and mean-

derings of the United States in this field. The British came later into this scene, after World War II; they could select and digest from our experience what seemed useful to them. Their judgment becomes an unusual opportunity to see ourselves as others see us.

Dr. Barker has put together a collection of clear and logical chapters written by himself and others concerned with the residential treatment of disturbed children. There is very little overlapping of subject matter. The writing styles are lucid and direct. There is little exploitation of innovation for innovation's sake or for grantsmanship's sake. The book could serve as a solid checklist for the fundamental ingredients of proper inpatient care and treatment of children.

The book shows sensitivity not only for the children themselves but for staff members as well. Careful attention is given to diagnosis and classification and also to the need for medical appraisal. Staff nurses seem to carry the main responsibilities with the children rather than the child-care workers relied on so much in the United States. Schooling is stressed as an integral part of the program. Treatment modalities lean toward behavioral modification, but psychoanalytic interpretations are employed judiciously and medications are used when really needed.

A significant difference between treatment programs in Britain and the United States is the relative smallness of the residential units in Britain. This seems to contribute appreciably to more individual attention without producing undue strains on the staff. Considerable emphasis is placed on careful, continual integration of the hospital services with all of the other family and community resources before, during, and after the hospital stay. The writers deplore the fact that there is only one academic unit of child psychiatry in Britain as well as the fact that the National Health Service accords rather scanty recognition to child psychiatry. We in the United States know these problems, too. The authors offer regrets for the absence from most treatment units of any staff for research and for the paucity of vigorously scientific studies of the actual treatment processes.

For perspective, Dr. Barker suggests the following:

> Long-term follow-up studies of child psychiatric patients should be treated with reserve. Inpatient care might be compared with one instrument in an orchestra, the music of which should be judged with and without that instrument. Consideration of inpatient treatment on its own is liable to lead to results as fallacious as judging the potential of a double-bass simply on what it can achieve played as a solo instrument.

ROBERT P. KEMBLE, M.D.
South Hadley, Mass.

The Psychoanalytic Forum, Vol. 5, *edited by John A. Lindon, M.D. New York, N.Y., International Universities Press, 1975, 430 pp., $15.00.*

The jacket of this volume carries the names of 68 "authors," which may be a record of some sort. In spite of this fact, the book does not come across in the usual desultory fashion of multiauthored books because the editor, John A. Lindon, has done his work well. In my opinion, he has successfully marshaled the contributions of these many and varied psychoanalysts into a readable and valid book.

Dr. Lindon has strictly limited the writing to nine clearly defined topics. Each topic is introduced by one well-known person, who presents his or her view of the particular issue. Then follow 6 to 10 shorter essays, all directly related to the primary topic, although often at variance with the point of view of the major presentation.

The quality of the comments varies, of course, but all address the central issue, a tribute to the editor as well as to each contributor. One feels when reading these papers that one is sharing an open meeting with people of strong but respectfully varying opinions. It is the sort of thing one wants from national meetings but, sadly, seldom gets. Each section gives the main author space for rebuttal, which makes for much more interesting and rounded reading. Because the topics are so varied, each of the nine will be identified in this review.

Harold F. Searles writes on "Violence in Schizophrenia." He stirs up the most controversial issue of the entire volume, namely, how much the personality of the therapist has to do with violence in the patient. Charles W. Wahl then presents some thoughtful material on "Psychoanalysis of the Rich, the Famous and the Influential," a subject about which all therapists must be concerned, to some degree at least. Again, the countertransference aspects come in for some heavy debate.

John C. Solomon addresses himself to "The Incredible Sixties: Psychodynamics of Youth," about which little is really known, even after one reads the seven responses. Stuart S. Asch presents some carefully thought out clinical and theoretical data on "Some Superego Considerations in Crime and Punishment." The respondents to his paper are well tuned to his tempo. Robert J. Stoller initiates some difficult polemics on the topic "Healthy Parental Influences on the Earliest Development of Masculinity in Baby Boys." Socarides, Mahler, De Saussure, Jossely, and Bowlby each has a great deal to say in response to this article.

Joseph M. Natterson writes on "Extra-Analytic Transference: A Two-Way Tide." This entire section is most delicately done by all of the writers. It will provoke thought in the careful reader. Frederick Kurth writes on "Projective Identification, Analyzability and Hate." The same range of theoretical comments, including the Kleinian perspective, can be found here as in other sections of the book. Melitta Sperling writes, in the way only she could have written, about "Somatic Symptomatology in Phobia." Her article is followed by interested praise and strong disclaimers by the discussants, all written before news of her death.

The last section of the book is the weakest: Hanna Segal writes on "Delusions and Artistic Creativity: Some Reflections on Reading William Golding's *The Spire*." This part of the book is interesting but of very little practical value to the average reader of this journal. Those who like this sort of thing have all they want in the analytic journals. It just did not seem to belong with the rest of this book. For the practitioner who must rely on reading to keep his perspectives clear, however, the bulk of this volume will prove valuable.

RAYMOND HEADLEE, M.D.
Milwaukee, Wis.

Principles of Family Psychiatry, *by John G. Howells, M.D., D.P.M. New York, N.Y., Brunner/Mazel, 1975, 446 pp., $17.50.*

Principles of Family Psychiatry is the latest in a scholarly series covering a wide variety of psychiatric subjects by Dr. Howells. In this volume he continues to display a depth of

knowledge and creativity that casts light not only on the field of family therapy but on psychiatry in general.

The scope of the book is quite broad—broader in fact than the title implies. What makes it possible to cover so much territory in one book is the excellent organization. One has the feeling that any information in the book could be relocated at a later date with very little effort.

As one would expect, the book contains an extensive analysis of the family—its functions, its dynamics, its psychology, and its psychopathology. Considerable space is devoted to this subject, with examinations of such areas as the role of individuals, communication among family members, and communication between the family and the rest of society. Dr. Howells presents a conceptual model of the family and then uses this model to help elucidate some ambiguous areas of psychiatric theory.

For example, family process is related to personality development and normal functioning as well as to somatic complaints, problems of the elderly, and many other areas of psychiatric disorder. In addition to examining the etiology of these disorders, Dr. Howells offers concrete suggestions for treatment, effective therapy goals, and organization of a family psychiatric service.

Probably the most innovative aspect of this volume is the section on the nosology of psychopathological conditions. Dr. Howells offers an extensive, well-grounded alternative to the traditional categories of diagnosis. It seems unlikely that this nosology will replace the terms currently in use, but it does provide the clinician with a valuable conceptual framework and concrete criteria for the evaluation of various "borderline" states. There is also an interesting section on schizophrenia in which this condition is subdivided in such a way as to make the diagnostic label more useful in the choice of treatment.

In summary, Dr. Howells offers an overview of family theory and therapy that should prove quite useful to those who wish to become more familiar with the area. He also offers a conceptual framework and a standardization of terms that should prove valuable to those of us already engaged in the practice of family psychiatry.

DAVID MENDELL, M.D.
Houston, Tex.

Training in Child Psychiatry in Canada, *edited by Dr. Paul Steinhauer. Toronto, Ont., Canada, Laidlaw Foundation, 1975, 114 pp., $3.00 (paper).*

To read this book is to regret that one was not part of its development. It records a two-and-a-half-day workshop at Val-David, Que., Canada, where 41 participants from all but one of the psychiatric training centers in Canada met in May 1974 to discuss four background papers that had been circulated in advance. Those position papers as well as the final presentation by a fifth contributor are reproduced in full in the second section of this book.

The first section is a masterful summary of the discussions; it is concise, terse, pithy, and yet reflective of the diversity of opinions expressed and the ardor of their protagonists. Dr. Steinhauer organized his overview of the workshop around nine key themes. He presents not only positions that all the participants could agree upon but also the dissenting views that many issues evoked. The result is a cornucopia of rewards for any reader. By no means confined to problems of training in Canada or to controversies within child psychiatry, the discussions range over the entire field of psychiatry and its place within medicine, within the broader fields of health and mental health, and within the society that supports it.

To imply that a review could give more than a suggestion of what this small volume contains would be an injustice to its editor and a disservice to its potential readers. The following are no more than isolated samplings of the kinds of questions the participants grappled with:

Recognizing that little has been achieved to eliminate mental health problems in the community, how can one argue for the relevance, efficiency, or even the validity of the specialty of psychiatry? What is the appropriate place for the psychodynamic/psychoanalytic model? Has the family model been oversold? Is the concept of effective consumer participation in planning and organizing services only a myth perpetuated by sociologists? How is training in child psychiatry best woven into the fabric of general psychiatric residency training? What is the ideal relationship between child psychiatry and pediatrics, between psychiatry and medicine, and between psychiatry and other mental health professions? What should residents learn, how should they learn it, and how should they organize and apply what they have learned?

The book is short, its content is full, and its style is easy. It is highly recommended.

ROBERT J. CAMPBELL, M.D.
Katonah, N.Y.

Practical Psychiatry for the Primary Physician, *by James R. Hodge, M.D. Chicago, Ill., Nelson-Hall, 1975, 345 pp., $15.00.*

Any psychiatrist who provides consultation to or teaches nonpsychiatric physicians soon accumulates a bookshelf of resources to which he can refer them. A practicing nonpsychiatric physician who wishes to read psychiatry is a rare treasure to be treated carefully, with respect and thoughtful guidance. To refer such a person to standard introductory psychiatry texts usually serves to drown his curiosity and enthusiasm in a flood of irrelevant detail.

The medical practitioner usually wants something that is clinically relevant and practical, uses a minimum of jargon, avoids unnecessary emphasis on psychopathology and theoretical dogma, and focuses primarily on doctor-patient relationships. By far the best book available for this purpose is Michael Balint's classic, *The Doctor, His Patient and the Illness* (1). The principal drawback to Balint's book is that one needs a fair amount of clinical sophistication and psychological mindedness to actually read it through and to be able to profit from the experience.

Dr. Hodge has provided a very useful single-author volume for the medical practitioner who is rediscovering psychiatry but is not yet ready to read Balint, or who needs an understanding of basic practical psychiatry, which Balint does not provide in quite the same way. In comparing this book with Balint's I do Hodge no disservice: Hodge acknowledges his debt to Balint throughout this book.

The strengths of Hodge's book lie in its practicality and commonsense approach. His presentation of the material is fair, balanced, and heavily laced with personal opinions and experiences, which are carefully labeled as such. In an engaging style, the book emanates practical clinical know-how. Although everyone will find things to disagree with here, I particularly liked the author's chapters titled "Principles of

Psychotherapy," "Strategies of Psychotherapy," and "Office Psychotherapy." Although the book is written for the nonpsychiatrist, I myself frankly found these chapters very instructive.

Features that may be less attractive to some readers stem from the author's tendency to skimp on detail and depth, presumably to enhance readability. Chapters particularly lacking in this regard are "Psychoactive Medications" and "Marital Conflict." Other chapters, although limited in scope and perhaps elementary in presentation, seem appropriate for the intended audience.

In summary, this is a good book for psychiatrists to skim if they wish to be familiar with potential resources for nonpsychiatrists. It is highly recommended for psychiatrists who want a good model of format and style for instructing nonpsychiatric physicians. It should also be popular with any physician who enjoys reading how an obviously skilled clinician deals with everyday problems of medical practice.

MARTIN R. LIPP, M.D.
San Francisco, Calif.

Down's Syndrome (Mongolism): Research, Prevention and Management, *edited by Richard Koch, M.D., and Felix F. de la Cruz, M.D. New York, N.Y., Brunner/Mazel, 1975, 235 pp., $10.00.*

Books that result from conferences are frequently eclectic in their treatment of the alleged common theme; this book is no exception. Nevertheless, it should not be dismissed lightly by the practicing physician, the medical educator, or anyone else who is interested in the mental health of families who have to cope with the presence of a chronic congenital handicap in one of their members. Its eclectic aspects stem directly from its subject matter, which is many faceted.

The conference from which these papers proceed was organized by two pediatricians and the father of a youngster with Down's syndrome. It was sponsored by the National Association for Retarded Citizens, organizations of parents of children with Down's syndrome, and the Mental Retardation Branch of the National Institute of Child Health and Human Development. The papers were prepared for the purpose of answering many of the questions that intelligent and concerned parents ask these days about Down's syndrome and about the prospects of children born with this condition.

Three of the papers deal with aspects of biochemical balance. Three deal with topics relevant primarily to the adult with Down's syndrome—employment, community mobility, and sexuality. Four papers deal with early intervention strategies based on psychoeducational techniques, two deal with longitudinal studies indicating the norms of development for this group of children as they grow up, and one deals very candidly with "Present Approaches to Therapy in Down's Syndrome." As a documentation of the state of the art in 1973, this book has both current and historical significance for physicians and child development specialists as well as parents.

Twenty-five years ago it was the usual practice for physicians to recommend early institutionalization of the mongoloid baby. Indeed, it was not uncommon for the child's father to be advised to have the infant placed directly from the newborn nursery so as not to let his wife become attached to "it." Until about 10 years ago, most data reported about the potentials for development of infants with Down's syndrome were based on observations made on children in institutions. We now know that the very process of caring for the children in this way considerably reduced their effective functioning. One of the contributions of this volume is to provide documentation based on creditable research rather than on isolated instances showing the changed expectations for developmental and social quotients obtained at various ages by children and adolescents with Down's syndrome raised at home. It makes clear that the physician jeopardizes his own credibility if he glibly tells parents that their infant will never walk or talk, as has so often happened in the past.

Parents have always been and continue to be intensely interested in the etiology of their children's disabilities. This parental interest is reflected in several of the papers included in this book. These papers also contain an implicit lesson for parents in the methods and conduct of research. Some of the very parents represented in this book lobbied the Senate Subcommittee on Appropriations for the U.S. Department of Health, Education, and Welfare in 1969. They wanted to be sure that Mary Bazelon Coleman would be funded for her studies on the role of serotonin in Down's syndrome. At the conference in 1973 they heard her give a straightforward and detailed account of the results of treatment with 5-hydroxytryptophan; the results were largely negative.

Nevertheless, hidden in Dr. Coleman's paper is an important observation:

> One of the major conclusions of our study relates to the depression and despair that pediatricians induce in the parents of Down's Syndrome patients by informing them at birth of the coming disability of their child. . . . The whole area of informing and supporting parents regarding the diagnosis and prognosis of a Down's Syndrome child during the early months of life is identified by this study as an area which needs research. (p. 114)

Psychiatry has little to contribute to the prevention of Down's syndrome, and it falls relatively infrequently to the psychiatrist to communicate this diagnosis. However, this process is fraught with risk for parents directly and for their infants indirectly. Not a single psychiatrist contributed to the body of this book; paradoxically, this constitutes the prime reason why psychiatrists, especially those in teaching positions, should both own and loan it.

ELIZABETH M. BOGGS, PH. D.
Hampton, N.J.

What is Psychotherapy? Parts I and II. Proceedings of the 9th International Congress of Psychotherapy, *edited by T.-E. Mogstad and F. Magnussen. New York, N.Y., S. Karger, 1975, 617 pp., $67.50.*

This collection of papers from the 9th International Congress on Psychotherapy in Oslo, Norway, is both extensive and expensive, the one attribute presumably justifying the other. The more than 100 very brief articles by as many different authors do not explore their topics in any great depth. The theme of nearly all of the papers seems to be that Freud is not enough.

The articles begin by labeling psychoanalytic therapy

"pseudoscience," note the "bankruptcy in the individual dynamic model," and conclude that psychotherapy today has refused to be limited to conventional interviews but has spilled over into activities beyond the individual patient. The participants of the conference seem motivated to elaborate beyond the plain and simple Freudian meaning of psychotherapy, with the evident goals of reaching a consensus, attaining greater efficiency, and providing greater adaptability to various social situations.

A few writers plead for training in self-restraint and for gaining new insights without losing sight of the values and knowledge provided by the pioneers of analysis. Chessick seems to make the most notable effort to integrate traditional psychotherapy and the newer therapies.

The expense of the book may be justified by the fact that it demonstrates the amazing range of variations in psychotherapy that exist worldwide. Two opening lectures state that psychotherapy molds the individual into his society—into a system of secular ethics, which, according to Szasz, is coercive, or into a way of realizing the image of man in actual socialistic life circumstances, which, according to a Marxist, makes life useful. The following contributions cover such remotely related issues as family therapy, systems theory, behavior therapy, philosophy, treatment of children, and social psychiatry.

Most of the well-known contemporary authorities (Frank, Strupp, Sifneos, etc.) are included in this volume; most of them restate what they have said before. It is interesting that the most quoted authors are (in order of frequency of quotations) Freud, Malan, Frank, Wolpe, Binswanger, and Wolberg.

The greatest reader interest will be attracted to the articles on autogenic training, Zen, and the roles of the shaman and the folkhealer in Africa and India.

The greatest weakness in the field of psychotherapy today appears to be the scarcity of articles on research in psychotherapy. Except for the work of a group in Boston, the research articles presented at the Oslo meeting appear to be limited to narrative reports of individual clinical experiences. In spite of their great fascination in revealing unique situations, these solitary studies simply show that psychotherapy today has yet to mount a program of decisive research to establish its real worth.

Detroit, Mich.

Depression: Concepts, Controversies, and Some New Facts, *by Eugene E. Levitt and Bernard Lubin. New York, N.Y., Springer Publishing Co., 1975, 163 pp., $8.50.*

The authors of this book would have done well to select a more appropriate title than simply *Depression*. This presentation is not really a book but a monograph; it deals with the results and interpretations of a special type of study. Using a questionnaire method of investigation, the authors sampled a population of 3,011 individuals throughout the United States to determine whether significant correlates to depression could be identified.

Their findings can be briefly summarized. Depression seemed to be more prevalent among older people and more evident in women than men. The authors also found a negative correlation between depression and education level and a higher evidence of reported depression among people of lower or moderate economic status who had recently suffered economic reverses. Black women in particular showed a high degree of depression. It was equally distributed among married and single people. Contrary to recent reports, people in high-prestige occupations, such as medicine, showed less depression than those in low-prestige occupations.

The difficulties inherent in this type of investigation are well known to anyone who has attempted epidemiological research. To begin with, in spite of the authors' lengthy review of the relevant literature and their discussion of methodology, the validity of their findings can be questioned on several levels. For instance, the levels of significance are frequently weak: the male-female correlation achieved only a 1% level, and the income correlations achieved only a 0.1% level.

Second, it is always difficult to know what is actually being detected in a study of this type. The introductory discussion of the nature of depression—what it may be as a mood, as a reaction, as a clinical condition—is insufficient and simultaneously too extensive to set the stage for the report that follows. This problem stems from the fact that rather than reconceptualizing the problem of depression in the light of "some new facts," as they set out to do, the authors have produced, essentially, an extended journal-type article with findings worth publishing and clues to further research but without the depth they originally promised.

It would have been much more satisfying if they had let the reader know early on what he was going to encounter, rather than preparing him for something that never happened. "Mountains will be in labor," said Horace, "and an absurd mouse will be born."

There is an important place in the psychiatric literature for the monograph format. Reorganized, the material presented in this book would have been better published as such rather than in its present form.

FREDERIC F. FLACH, M.D.
New York, N.Y.

The Diagnosis and Treatment of Alcoholism, *by Gary G. Forrest, Ed.D. Springfield, Ill., Charles C Thomas, 1975, 251 pp., no price listed.*

The author, who supervises a military alcoholism rehabilitation program, addresses himself to the broad field of clinical workers in alcoholism treatment programs. He provides background information as well as "how I do it" chapters that should be helpful, especially to alcoholism counselors with limited professional background and professionals coming into the field with limited experience with alcoholic patients. Experienced professionals will find the book helpful, especially if it supports their particular viewpoints, and quite useful in staff training.

The first section of the book presents background information about the definition of alcoholism, the stages of alcoholism, and personality characteristics of the alcoholic patient. One might criticize Forrest's definition of "alcoholism" as distinct from "problem drinking" as being a bit too restrictive and placing too much emphasis on physical complications rather than evidence of true addiction. His use of the term "chronic alcoholism" for the most advanced stage is a redundancy because alcoholism is chronic by definition. In discussing the meaning of the drinking experience, emphasis is given to relief of pain; the pleasure provided by alcohol is not given sufficient importance. However, Forrest says

the following, with which I most heartily agree: "It is my impression that the addiction per se is the focal point to be dealt with therapeutically" (p. 60).

The second section of the book, Strategies of Treatment, discusses individual and group psychotherapy, Alcoholics Anonymous, residential treatment, and behavior therapy. The chapters on psychotherapy are the best in the book; these will be quite helpful to new counselors because they offer optimism and encourage an open, involved approach. Forrest emphasizes warmth, empathy, and genuineness; he is a directive Rogerian. His description of his results might sound like "transference cures" to many, but he does not address countertransference issues. Nevertheless, the techniques he suggests are sound, although he may be a bit overenthusiastic when he claims 85% effectiveness (p. 73) without substantiating data.

Two interesting practical suggestions can be found in the chapters on psychotherapy: no more than 40% of a treatment staff for alcoholic patients should be made up of "recovered" alcoholics, to avoid one-sidedness; in group treatment, there should be some group members with at least six months' sobriety to serve as role models.

Other discussions in this section give superficial coverage to such topics as detoxification, genetics, hospital programs, and behavior therapy.

The third section of the book is a mixed bag of brief theoretical essays and small pilot research studies. Forrest discusses the need for self-disclosure by the alcoholic for recovery, drinking periods as symbolic death and recovery as rebirth, and the "hide-and-seek" game of the hidden alcoholic in the military. He does better when he gets back to treatment, especially in the chapter titled "Resolution of the Alcoholic Power Fantasy." The research studies on treatment effectiveness are of the pilot variety—e.g., with small samples and self-selected "controls." These studies suggest the capability of the author and his staff to do more definitive research on their clinical work.

The book contains certain errors, e.g., the following: "Significant numbers of alcoholics die annually as a result of the DT's, in spite of medical intervention" (p. 21); diazepam and chlordiazepoxide do not reduce anxiety but alcohol does (p. 42); high blood pressure and diabetes are "clearly a part of the overall clinical picture" in late-stage alcoholism (p. 58); and "Intravenous and oral fluid ingestion [should be used] to counteract dehydration" (p. 125).

With prompt medical attention, the mortality rate from delirium tremens is very low, and a dropping alcohol blood level leads to overhydration. However, taken as a whole, with its good and bad points, this book is a useful addition to a staff training library.

ROBERT A. MOORE, M.D.
San Diego, Calif.

Growth and Change of Schizophrenic Children: A Longitudinal Study, *by William Goldfarb, M.D., Ph.D. Washington, D.C., V.H. Winston & Sons (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1975, 271 pp., $10.95.*

In their studies of schizophrenic children and their families during the past two decades, William Goldfarb and his collaborators at the Ittleson Center have shown how clinical research and humane care can enrich each other (1, 2). This book is a report on changes in adaptive functions of 40 schizophrenic children who received residential treatment when they were between the ages of 7 and 10 years. The children were tested and rated on a variety of measures at several points during the course of treatment. The results were assessed for trends over time and comparison with normal children. The 40 measures included IQ tests, neurological assessments, academic achievement scales, perceptual tasks, and a variety of rating scales.

On many dimensions of conceptual behavior, communication, motor coordination, and perceptual skill, the schizophrenic children showed definite improvement in response to intensive educational, social, and therapeutic influences. However, most of the children did not reach normal levels, and there were great individual differences. On several dimensions the children's initially marked abnormalities persisted: muscle tone (hypertonia and hypotonia), activity (hyperactivity and hypoactivity), and receptor function (underreaction or overreaction to delayed auditory feedback and sudden noise). The children's deviant receptor responses were consistent with the idea that their difficulties in self-regulation may be related to disturbances in meaningfully organizing perceptual information and deploying attention. Goldfarb suggests, however, that deficits even in these areas may be remedied with newer educational techniques.

Anyone who has conducted longitudinal clinical research will appreciate the difficulties that must have been encountered in conducting this study: changes in therapeutic and educational ideas and methods, staff turnover, and, above all, the need to treat each child as an individual. These factors must be kept in mind in evaluating the results. One would like to cite this study as evidence of the value of intensive residential treatment, which it supports. However, the study is limited because we do not know about the universe of disturbed children from whom these fortunate 40 were drawn, and there is no adequate control group of schizophrenic children who were treated in other ways (e.g., day schools with active parent involvement).

In his previous studies as well as this one, Goldfarb has clarified some dimensions of the heterogeneity of the population of children who are diagnosed as schizophrenic. They come from different kinds of families, differ in neurological integrity, and present with a broad range of intellectual, social, and emotional disabilities. How they differ, as demonstrated in this book, may be more apparent than how they are the same. The phenotypic variance probably reflects important genotypic distinctions.

Until the fundamental lines are drawn between subgroups of the childhood schizophrenias or along the schizophrenic or atypical spectrum, all research on severe psychiatric disturbances of childhood will be hampered. One contribution to this effort is Goldfarb's attempts at distinguishing subgroups clinically. Advances in biological research may be dependent on this clinical investigation and, in turn, may provide new criteria for subgrouping.

For most readers, the main attraction of this book will be its summary of Goldfarb's balanced viewpoint on ego disturbances in childhood schizophrenia. The book has two relatively minor limitations. First, the title may imply that it is a long-term longitudinal or outcome study of childhood schizophrenia rather than a study of the impact of residential treatment during three years. Second, the 130 pages of tables will be of little interest to any but the most specialized researcher. Perhaps they could have been made available in another way to those interested. A more substantial concern has to do with the analysis of the data. With so many measures, many of which tended to cluster together, I wonder why

more sophisticated, multivariate analysis was not attempted to explicate underlying dimensions and, perhaps, to assist in defining subgroups.

DONALD J. COHEN, M.D.
New Haven, Conn.

Mental Health: The Public Health Challenge, *edited by E. James Lieberman, M.D. Washington, D.C., American Public Health Association, 1975, 287 pp., no price listed.*

The general purpose of this book appears to be to stimulate greater interest in mental health services among public health administrators. It probably will succeed in this endeavor because it presents the mental health dimensions of subject areas that are familiar to public health personnel—e.g., prevention, training, services, policy making, and social issues. The last chapter, on information sources, is comprehensive and of value to everyone interested in the field of mental health.

By using a definition of prevention that includes primary (the removal of causes), secondary (early treatment), and tertiary (rehabilitation), the book makes all mental health services legitimate for public health personnel. Some of the articles give the impression that the field of mental health has the responsibility and the capability to solve social and environmental problems that have theoretical, direct, or indirect impact on the well-being of individuals or communities. These include, but are not limited to, the following: poverty, discrimination, unemployment, crime, delinquency, education, and divorce. This may attract and challenge some public health personnel, but it might create a serious reluctance for others.

The field of public health has been concerned traditionally with primary prevention. Lemkau, with his usual candor, states that "the pathological mechanisms for the most important 'functional' mental illnesses, affective disorder, schizophrenia, neuroses, and personality disorders remain conjectural or unknown." He also states that "some causes of mental disorders are known, but the causes of most are unknown, or at least unproven." He then lists as known causes poison, infection, genetics, nutrition, physical trauma, and general systemic disease. Another author in the volume, however, is undaunted by such knowledge, writing of his interest in improving the quality of life and well-being of patients, "not merely averting pathology." This author states that his approach to primary prevention is based on a "socio-psycho-cultural-educational rather than a medical model."

It is well to remember, while reading the expositions of the various authors, that the admonition at the beginning of the book says that the ideas and opinions presented by the authors are their own and do not necessarily represent the view or policies of the American Public Health Association. That is what makes the various articles interesting.

JAMES V. LOWRY, M.D.
San Diego, Calif.

Studies of Schizophrenia. British Journal of Psychiatry Special Publication 10, *edited by M.H. Lader. Ashford, Kent, England, Headley Brothers, 1975, 160 pp., $9.00 (paper).*

This publication makes available in convenient form the papers read at the World Psychiatric Association symposium Current Concepts of Schizophrenia, which was held in London in November 1972. The authors represent 14 countries of Europe and 3 of the western hemisphere; the reader in the United States thus obtains access to a great deal of unfamiliar work. As Lader points out in his foreword, there are great differences in the concepts used in different countries.

Opening remarks by Dr. Howard Rome and Sir Martin Roth outline recent developments in research on schizophrenia. There follow four chapters on diagnostic concepts, five on genetic and nature-nurture aspects, five on schizophrenia and the community, four on psychotherapy, and nine of other aspects of treatment. All are brief and concise presentations of useful material.

Particularly worthy of notice is the chapter by Tienari, of Oulu, Finland, who summarizes results of concordance rates of monozygotic twin studies reported between 1928 and 1970 and presents up-to-date results of his study of all pairs of male twins born in Finland between 1920 and 1929. His 1963 report found no concordance in 16 pairs of monozygotic twins with 1 schizophrenic member. A total of 1,432 twin pairs were reviewed again in 1969 and 1970: preliminary results now support a concordance rate of 15% in monozygotic pairs and 7.5% in dizygotic pairs for schizophrenia or paranoid psychosis.

Another chapter of special interest is that by Kolyaskina and Vartanian of Moscow, who report findings that suggest that patients with continuous (nonrecurrent) schizophrenia and their relatives show brain antibodies in their systems.

The topic of schizophrenia and the community is covered in articles from England, the United States, Canada, Hungary, and Rumania; it is evident that similar problems in attempts to return schizophrenia patients to the community arise in different countries.

This is an admirable compendium of papers that shows the diversity of approaches to schizophrenia throughout the world. Although uneven in scientific caliber, it fulfills its stated goal of presenting the views of leading researchers in the field in a relatively concise and readable form. It can be recommended to residents in psychiatry as a source of information on schizophrenia that is not found in standard textbooks or American journals.

Lederle Laboratories introduces

Loxitane™

LOXAPINE SUCCINATE

Lederle

A NEW CHEMICAL ENTITY FOR THE MANIFESTATIONS OF SCHIZOPHRENIA

Product of a decade of research and clinical evaluation by Lederle Laboratories, LOXITANE is a dibenzoxazepine, representing a new subclass of tricyclic antipsychotic agents. It is chemically distinct from the phenothiazines, thioxanthenes and butyrophenones.

A program of 31 studies[1] by 18 investigators included 11 controlled studies of 441 adult patients to determine efficacy of LOXITANE by comparing it with two reference agents, chlorpromazine and trifluoperazine.

Patient types	No. of Studies	No. of Loxapine Subjects	No. of Chlorpromazine Subjects	No. of Trifluoperazine Subjects
Acute Schizophrenic*	5	98	70	27
Chronic Schizophrenic†	6	123	39	84
Totals	11	221	109	111

*Studies carried out with newly admitted patients with acute schizophrenic symptoms.
†Studies carried out with patients resident in psychiatric wards for at least a year.

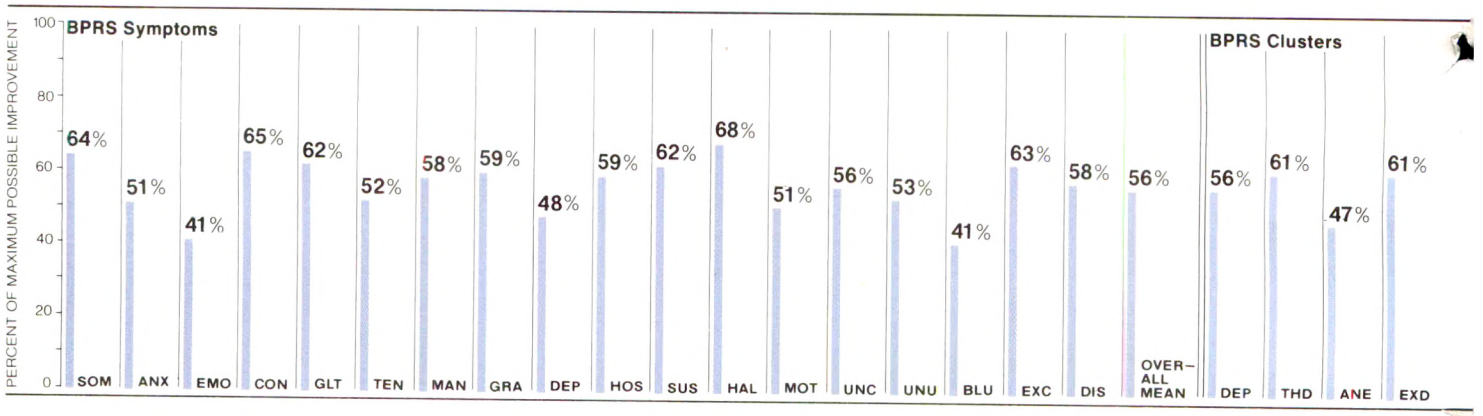
Psychiatric and behavioral symptoms were assessed by the Brief Psychiatric Rating Scale (BPRS) and the Nurses' Observation Scale for Inpatient Evaluation (NOSIE). Response was measured by statistical analysis comparing symptom severity before and after treatment. The controlled studies demonstrated the efficacy of LOXITANE and the two reference agents. The graphs that follow show the substantial reduction in schizophrenic symptoms achieved by the LOXITANE patient group as expressed in terms of percent of Maximum Possible Improvement.

1. Data on file, Clinical Research Department, Lederle Laboratories

Now in schizophrenia—efficacy that speaks for itself..

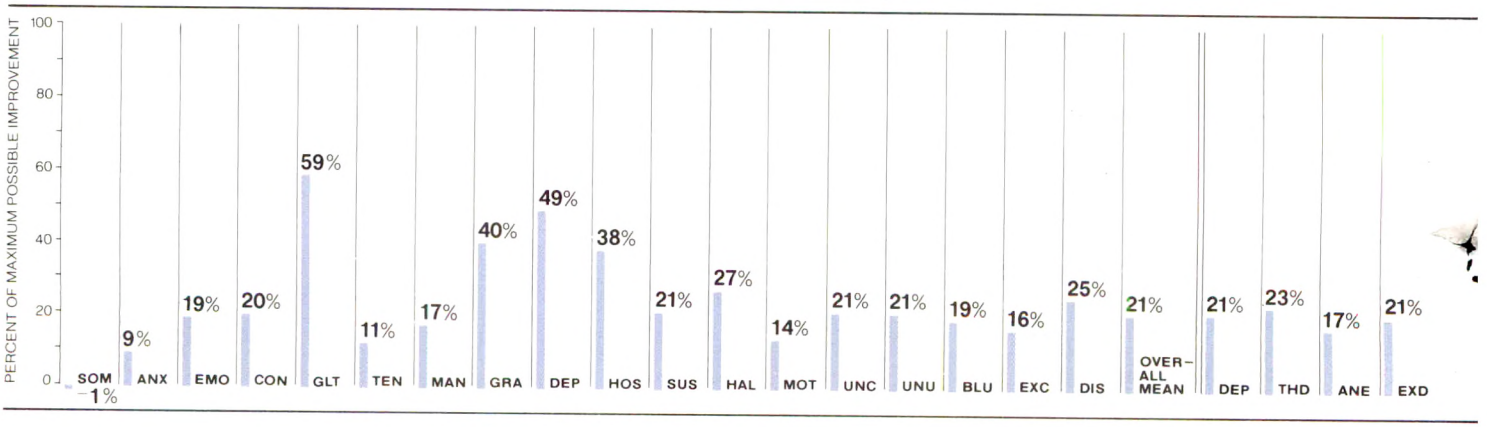
SEE LAST PAGE OF THIS ADVERTISEMENT FOR FULL PRESCRIBING INFORMATION.

Lederle Laboratories introduces



Loxitane™
LOXAPINE SUCCINATE
Lederle

SUBSTANTIALLY REDUCES THE SYMPTOMS OF SCHIZOPHRENIA



In 5 studies involving 98 acute schizophrenic patients treated for 3 to 6 weeks...

Patients treated with LOXITANE Loxapine reached an average of 56% of Maximum Possible Improvement in 18 symptoms and symptom clusters

In 6 studies involving 123 chronic schizophrenic patients treated for 8 to 12 weeks...

Severity of schizophrenic symptoms was appreciably reduced despite the typically lower responsiveness of the chronic patient

In 31 long-term, dose-range finding and controlled efficacy studies involving 469 patients...

Certain favorable trends were exhibited in the LOXITANE side effects profile, but these require further tests and broader clinical experience for confirmation

No endocrine abnormalities have been reported with LOXITANE. Hepatotoxicity manifested by jaundice or biliary stasis has not been observed. Transient liver enzyme changes, however, have been reported, but it has not been determined whether they are related to LOXITANE administration.

Although a few cases of changes in ECG have been reported, a causal relationship to LOXITANE has not been established. Clinical experience with LOXITANE has not demonstrated ocular toxicity; however, the possibility of its occurrence cannot be ruled out at this time. Manifestations of adverse effects on the central nervous system other than extrapyramidal symptoms have been encountered infrequently, and drowsiness, when it occurs, is usually mild and subsides with continued therapy. Skin rashes of uncertain etiology have been observed in a few patients during the hot summer months; therefore the possibility of phototoxicity and/or photosensitivity cannot be excluded.

In general, LOXITANE presents a profile of extrapyramidal side effects similar to that of other agents used in the treatment of schizophrenia. Parkinson-like symptoms and akathisia are usua not severe and can be controlled by reduction in LOXITANE dosage or by administration of antiparkinson drugs. Dystonia and dyskinetic reactions, while less frequent, may be more severe and may require reduction or temporary withdrawal of LOXITANE dosage, as well as treatment with anticholinergic agents. As with all antipsychotic agents, tardive dyskinesia ma appear in some patients on long-term therapy or after drug therapy has been discontinued. It is suggested that treatment w any antipsychotic agent be suspended should this reaction occ

Cardiovascular effects such as hypotension, hypertension, light headedness and syncope have been reported. Increased pulse rate has been reported in a majority of patients receiving antipsychotic doses. Anticholinergic effects seen with LOXITANE include dry mouth, nasal congestion, constipation and blurred vision.

See LOXITANE package insert for warnings and precautions ar for more detailed information concerning side effects.

Loxitane™
LOXAPINE SUCCINATE
Lederle

A range of dosage forms to suit the patient's individual needs

Supplied

Capsules	10 mg Green and Yellow	25 mg Green Two Tone	50 mg Green and Blue

Recommended Daily Dosage

Initial Dosage	MILD 10 mg b.i.d.	MODERATE 10 mg t.i.d. or q.i.d.	SEVERE 25 mg b.i.d.
First 7 to 10 Days	Increase dosage until psychotic symptoms are controlle Dosage should not exceed 250 mg/day Usual dosage during titration 50 to 150 mg/day		
Maintenance Dosage	Adjust to lowest effective level Usual maintenance dosage 60 to 100 mg/day Many patients are controlled with dosages as low as 2(to 60 mg/day		

SEE LAST PAGE OF THIS ADVERTISEMENT FOR FULL PRESCRIBING INFORMATION.

FOR ORAL USE

PRODUCT INFORMATION

DESCRIPTION

LOXITANE® *loxapine*, a dibenzoxazepine compound, represents a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines. Chemically, it is 2 - chloro - 11 - (4 - methyl - 1 - piperazinyl) dibenz [b,f] [1,4] oxazepine. It is present in capsules as the succinate salt. Each 1.36 mg of loxapine succinate is equivalent to 1 mg of loxapine.

ACTIONS

Pharmacologically, loxapine is a tranquilizer for which the exact mode of action has not been established. However, changes in the level of excitability of subcortical inhibitory areas have been observed in several animal species in association with such manifestations of tranquilization as calming effects and suppression of aggressive behavior.

In normal human volunteers, signs of sedation were seen within 20 to 30 minutes after administration, were most pronounced within 1½ to 3 hours, and lasted through 12 hours. Similar timing of primary pharmacologic effects was seen in animals.

Absorption of loxapine following oral or parenteral administration is virtually complete. The drug is removed rapidly from the plasma and distributed in tissues. Animal studies suggest an initial preferential distribution in lungs, brain, spleen, heart, and kidney. Loxapine is metabolized extensively and is excreted mainly in the first 24 hours. Metabolites are excreted in the urine in the form of conjugates and in the feces unconjugated.

INDICATIONS

LOXITANE *loxapine succinate* is indicated for the manifestations of schizophrenia.

CONTRAINDICATIONS

LOXITANE is contraindicated in comatose or severe drug-induced depressed states (alcohol, barbiturates, narcotics, etc.)

LOXITANE is contraindicated in individuals with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Safe use of LOXITANE *loxapine succinate* during pregnancy or lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the benefits of treatment be weighed against the possible risks to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from midpregnancy with doses of 0.6 and 1.8 mg/kg, doses which approximate the usual human dose but which are considerably below the maximum recommended human dose.

Usage in Children: Studies have not been performed in children; therefore this drug is not recommended for use in children below the age of 16.

LOXITANE, like other tranquilizers, may impair mental and/or physical abilities, especially during the first few days of therapy. Therefore, ambulatory patients should be warned about activities requiring alertness (eg, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

PRECAUTIONS

LOXITANE loxapine succinate should be used with extreme caution in patients with a history of convulsive disorders since it lowers the convulsive threshold. Seizures have been reported in epileptic patients receiving LOXITANE at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy.

Loxapine has an antiemetic effect in animals. Since this effect may also occur in man, loxapine may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

LOXITANE should be used with caution in patients with cardiovascular disease. Increased pulse rates have been reported in the majority of patients receiving antipsychotic doses; transient hypotension has been reported. In the presence of severe hypotension requiring vasopressor therapy, the preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine.

The possibility of ocular toxicity from loxapine cannot be excluded at this time. Therefore, careful observation should be made for pigmentary retinopathy and lenticular pigmentation since these have been observed in some patients receiving certain other antipsychotic drugs for prolonged periods.

Because of possible anticholinergic action, the drug should be used cautiously in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

ADVERSE REACTIONS

CNS Effects: Manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently. Drowsiness, usually mild, may occur at the beginning of therapy or when dosage is increased.

It usually subsides with continued LOXITANE therapy. The incidence of sedation has been less than that of certain aliphatic phenothiazines and slightly more than the piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported.

Extrapyramidal Reactions—Neuromuscular (extrapyramidal) reactions during the administration of LOXITANE *loxapine succinate* have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved Parkinson-like symptoms such as tremor, rigidity, excessive salivation, and masked facies. Akathisia (motor restlessness) also has been reported relatively frequently. These symptoms are usually not severe and can be controlled by reduction of LOXITANE dosage or by administration of antiparkinson drugs in usual dosage. Dystonic and dyskinetic reactions have occurred less frequently, but may be more severe. Dystonias include spasms of muscles of the neck and face, tongue protrusion, and oculogyric movement. Dyskinetic reaction has been described in the form of choreo-athetoid movements. These reactions sometimes require reduction or temporary withdrawal of LOXITANE dosage in addition to appropriate counteractive drugs.

Persistent Tardive Dyskinesia—As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movement of the tongue, face, mouth, or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Cardiovascular Effects: Tachycardia, hypotension, hypertension, light-headedness, and syncope have been reported.

A few cases of ECG changes similar to those seen with phenothiazines have been reported. It is not known whether these were related to loxapine administration.

Skin: Dermatitis, edema (puffiness of face), pruritus, and seborrhea have been reported with loxapine. The possibility of photosensitivity and/or phototoxicity occurring has not been excluded; skin rashes of uncertain etiology have been observed in a few patients during hot summer months.

Endocrine Effects: No endocrine abnormalities have been reported.

Anticholinergic Effects: Dry mouth, nasal congestion, constipation, and blurred vision have occurred; these are more likely to occur with concomitant use of antiparkinson agents.

Other Adverse Reactions: Nausea, vomiting, weight gain, weight loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, and polydipsia have been reported in some patients.

DOSAGE AND ADMINISTRATION

LOXITANE *loxapine succinate* is administered orally usually in divided doses two to four times a day. Daily dosage (in terms of base equivalents) should be adjusted to the individual patient's needs as assessed by the severity of symptoms and previous history of response to antipsychotic drugs. Initial dosage of 10 mg twice daily is recommended, although in severely disturbed patients initial dosage up to a total of 50 mg daily may be desirable. Dosage should then be increased fairly rapidly over the first seven to ten days until there is effective control of psychotic symptoms. The usual therapeutic and maintenance range is 60 mg to 100 mg daily. However, as with other antipsychotic drugs, some patients respond to lower dosage and others require higher dosage for optimal benefit. Daily dosage higher than 250 mg is not recommended. For maintenance therapy, dosage should be reduced to the lowest level compatible with symptom control; many patients have been maintained satisfactorily at dosages in the range of 20 mg to 60 mg daily.

HOW SUPPLIED

LOXITANE *loxapine succinate* is supplied in the following base equivalent strengths:

CAPSULES Hard Shell Printed "Lederle"

10 mg—Green and Yellow; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5360.

25 mg—Green Two Tone; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5361.

50 mg—Green and Blue; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5362.

A Timely New Book from The Joint Information Service

This latest Joint Information Service field study provides a concise, comprehensive overview of the complex matter of the very young American child and his mental health, and then describes in intimate detail seven unique programs for pre-school children with problems—from North Hollywood's Dubnoff Center, emphasizing education as its primary therapeutic modality, to Baltimore's Martin Luther King, Jr. Parent-Child Center, serving two housing projects, served by Johns Hopkins, and largely governed by its own people. All different in treatment approach and philosophy, the programs described are uniform in their dedication to innovation in improving service to the emotionally disturbed very young child, and, equally, to the emotional well being of all young children.

This thoughtful and perceptive description of what has been created by some of the best informed, most experienced and thoughtful specialists in mental health services for very young children should be welcome to all involved in the mental health of children and a casebook for those dealing with child and family mental health.

An articulate exposition of the immense problems and encouraging accomplishments in a particularly difficult area of endeavor . . . . Beyond their concern with the manifestly ill child, the authors intriguingly explore what may be needed to enhance the mental good health of all young children . . . . A significant contribution.

James N. Sussex, M.D.
President, American Association of Psychiatric Services for Children

Suspicious and hostile?

Consider the advantages of starting her on HALDOL® (haloperidol)

Acts promptly to control hostility and suspiciousness

Several clinicians have cited the special value of HALDOL haloperidol in controlling hostility, suspiciousness, ideas of persecution and other delusions associated with psychoses.[1-6] Symptom control is achieved rapidly, with many patients showing distinct improvement in a few days to a week[1,6]—frequently within a few hours when the intramuscular form is used for initial control of acutely agitated psychotic states.[7,8]

Usually leaves patients relatively alert and responsive

Although some instances of drowsiness have been observed, marked sedation with HALDOL haloperidol is rare. In fact, this drug has been reported to increase activity in some underactive patients, while in hyperactive patients it usually reduces activity to a normal level without somnolence. HALDOL haloperidol has been found to "normalize" behavior and produce a sensitivity to the environment that allows more effective use of the social milieu and the therapeutic community.[4]

Reduces likelihood of certain adverse reactions

HALDOL haloperidol, a butyrophenone, avoids or minimizes many of the problems associated with the phenothiazines. The most commonly noted side effects of HALDOL haloperidol—extrapyramidal reactions—are usually dose-related and readily controlled with antiparkinson drugs.

Transient hypotension occurs rarely; severe orthostatic hypotension has not been reported. HALDOL haloperidol is also unlikely to cause hepatic damage, serious hematologic reactions, photosensitivity reactions and skin rashes. Ocular damage and pigmentation changes have not been reported.

HALDOL®
(haloperidol)
tablets/concentrate/injection

highly specific control of disordered and disruptive behavior

For information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions, please turn page.

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

©McNeil Laboratories, Inc., 1975

HALDOL®
(haloperidol)
tablets/concentrate/injection

highly specific control of disordered and disruptive behavior

A Dosage Form for Every Need:

5 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg., 5 mg. and 10 mg.

An undetectable, tasteless liquid concentrate for the patient unable or unwilling to swallow tablets: 2 mg. per cc.

A rapid-acting injection for psychiatric emergencies: 5 mg. per cc., with 0.5 mg. methylparaben and 0.05 mg. propylparaben per cc., and lactic acid for pH adjustment to 3.4±0.2.

Indications: HALDOL haloperidol is indicated for use in the management of manifestations of psychotic disorders.

It is also indicated for the control of tics and vocal utterances of Gilles de la Tourette's syndrome.

Contraindications: HALDOL haloperidol is contraindicated in patients who are severely depressed, comatose, have CNS depression due to alcohol or other centrally-acting depressants, have Parkinson's disease or are hypersensitive to this drug.

Warnings: ***Usage in Pregnancy:*** Safe use of HALDOL haloperidol in pregnancy and lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the possible benefits of the drug be weighed against the potential hazards. A case of phocomelia in an infant whose mother received haloperidol along with a number of other medications during the first trimester of pregnancy has been reported (a causal relationship was not established in this case). Animals receiving 2 to 20 times the maximum human dose of haloperidol orally and/or parenterally showed increased incidence of resorption, reduced fertility, delayed delivery, dose-related pup mortality (presumably due to lack of maternal care reflecting CNS depression).

Usage in Children: Safety and effectiveness in children have not been established; therefore, this drug is not recommended for use in the pediatric age group.

General: Cases of bronchopneumonia, some fatal, have followed the use of major tranquilizers, including haloperidol. It has been postulated that lethargy and decreased sensation of thirst may lead to dehydration, hemoconcentration and reduced pulmonary ventilation. If these signs and symptoms appear, especially in the elderly, the physician should institute remedial therapy promptly. Although not reported with HALDOL haloperidol, decreased serum cholesterol and/or cutaneous and ocular changes have been reported in patients receiving chemically-related drugs. HALDOL haloperidol may impair the mental and/or physical abilities required for the performance of hazardous tasks such as operating machinery or driving a motor vehicle. The ambulatory patient should be warned accordingly. The use of alcohol should be avoided due to possible additive effects and hypotension.

Precautions: HALDOL haloperidol should be administered cautiously to patients: (1)—with severe cardiovascular disorders, because of the possibility of transient hypotension and/or precipitation of anginal pain. Should hypotension occur and a vasopressor be required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur. (2)—receiving anticonvulsant medication, because HALDOL haloperidol may lower the convulsive threshold. Adequate anticonvulsant therapy should be maintained concomitantly. (3)—with known allergies, or with a history of allergic reactions to drugs. (4)—receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione).

If concomitant antiparkinson medication is required, it may have to be continued after HALDOL haloperidol is discontinued because of the difference in excretion rates. If both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson agents, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used to control mania in cyclic disorders there may be a rapid mood swing to depression.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which usually were mild to moderately severe and reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Administration of antiparkinson drugs may be required for control of such reactions. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Persistent Tardive Dyskinesia*—Tardive dyskinesia may appear during long-term therapy or after therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. There is no known effective treatment. All antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports have appeared of mild and usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis. Agranulocytosis has rarely been reported and then only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice have been reported, although a causal relationship has not been established. ***Dermatologic Reactions:*** Maculopapular and acneiform skin reactions and isolated cases of photosensitivity and loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

Complete dosage information available in insert which accompanies each package (or on request).

The use of the injectable form is intended for the acutely agitated psychotic patient with moderately severe to very severe symptoms.

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed. 9/74

Where The Action Is—

For more than a decade the general hospital psychiatric unit has been the principal locus of inpatient treatment. This latest Joint Information Service national survey brings up to date its earlier—and the original—study of this important component of the psychiatric scene. It reveals that the remarkable rate of growth held up, showing an increase of 50 percent in the number of units between 1963 and 1971, and an increase of 46 percent in the number of admissions. And it verifies that general hospital psychiatry has become increasingly comprehensive, with an impressively high level of outpatient service, emergency service, and even consultation to community agencies. Indeed, the general hospital accounts for several times as much service and activity as the widely heralded federally supported community mental health center.

This study also involves the private psychiatric hospitals, which have not changed much in number but are admitting about 10,000 more patients than in 1964—and they, too, are providing a remarkably comprehensive program.

It's your responsibility to be well-informed about these extraordinarily significant and vital pieces of American psychiatric service. You can do so by sending the order form below.

Just published
4th edition

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

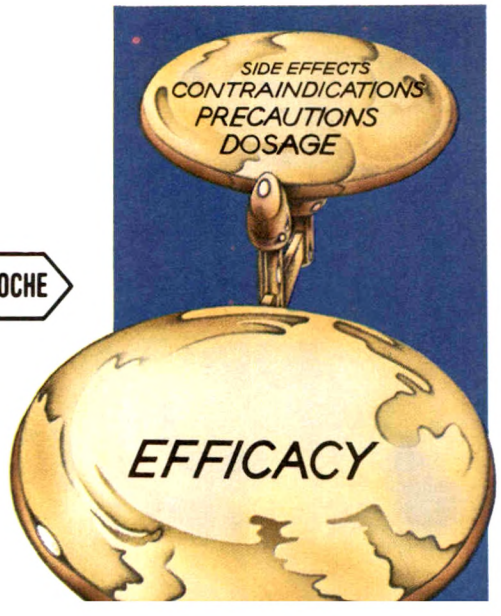
LIBRIUM®
(chlordiazepoxide HCl)
5 mg, 10 mg, 25 mg capsules

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.
Contraindications: Patients with known hypersensitivity to the drug.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.
Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.
Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.
Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

ROCHE
Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

SAFETY. IT'S A QUESTION OF BALANCE.

In choosing a tranquilizer for the patient whose excessive anxiety is disrupting psychotherapy there are a number of things to consider. One is effectiveness. A second is safety.



The first is more easily established. The second may be ascertained by comparison. In other words, with safety there is the question of balancing a drug's potential benefits against any potential risks.

When the antianxiety agent you are considering is Librium, you should know that it has a wide margin of safety.

The most common side effects of Librium are dose-related and thus largely avoidable. There appears to be a low incidence of drug dependence and tolerance. Librium rarely has any adverse effects on the cardiovascular or respiratory systems, and there are relatively few cases of known toxicity attributable to Librium.

You already know that Librium is effective. But you should also know that Librium, used in proper dosage, rarely interferes with mental acuity and thus is unlikely to interfere with the psychotherapeutic process. In addition, Librium is used concomitantly with many primary medications.

Librium. All in all, a very good balance.

The familiar refrain of depression: morning fatigue... sadness... anorexia... insomnia

Now, Merrell offers Norpramin (desipramine hydrochloride tablets N.F.) to effectively relieve these common manifestations of depression.

Norpramin also provides additional benefits in treatment of your patients.

- ☐ effectively relieves physical, psychological and emotional symptoms of depression
- ☐ minimal daytime sedation — important for patients who must be alert to perform daytime activities
- ☐ relief that may begin in 2 to 5 days — but full therapeutic effect is seldom seen before 2 weeks
- ☐ side effects rarely require discontinuation of therapy
- ☐ increases interpersonal responsiveness
- ☐ can help facilitate psychotherapy

Prescribe Norpramin to change the familiar refrain of depression in your practice.

Norpramin®
(desipramine hydrochloride tablets N.F.)

Brief Summary

Indications: Norpramin (desipramine hydrochloride tablets N.F.) is indicated for the relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Desipramine hydrochloride should not be given within two weeks of treatment with a monoamine oxidase inhibitor. Contraindications include the acute recovery period following myocardial infarction and hypersensitivity to the drug. Cross sensitivity with other dibenzazepines is a possibility.

Warnings: 1. Extreme caution should be used in patients: (a) with cardiovascular disease. (b) with a history of urinary retention or glaucoma. (c) with thyroid disease or those on thyroid medication. (d) with a history of seizure disorder. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. *Use in Pregnancy:* Safe use during pregnancy and lactation has not been established. 4. *Use in Children:* Norpramin is not recommended for use in children. 5. This drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. Therefore, the patient should be cautioned accordingly.

Precautions: This drug should be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with drugs of this class. If possible, dispense in child-resistant containers. It should be kept out of reach of children. Reduce dosage, or alter treatment, if serious adverse effects occur. Norpramin therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates and may cause exacerbation of psychosis in schizophrenic patients. Use cautiously with anticholinergic or sympathomimetic drugs. Response to alcoholic beverages may be exaggerated. In the concurrent administration of ECT and antidepressant drugs one should consider the possibility of increased risk relative to benefits. Discontinue as soon as possible prior to elective surgery because of possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients on desipramine hydrochloride. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy: the drug should be discontinued if there is neutropenia.

Adverse Reactions: *Cardiovascular:* hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke. *Psychiatric:* confusional states (especially in the elderly), hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis. *Neurological:* numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus. *Anticholinergic:* dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, hypotonic bladder. *Allergic:* skin rash, petechiae, urticaria, itching, photosensitization, edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs. *Hematologic:* bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue. *Endocrine:* gynecomastia, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels. *Other:* jaundice (simulating obstructive), altered liver function; weight gain or loss, perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia. *Withdrawal Symptoms:* Though not indicative of addiction, abrupt cessation after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: *The usual adult dose:* 50 mg. three times daily; increase if necessary after 7 to 10 days to maximum of 200 mg. daily. Dosages above 200 mg. per day are not recommended. *Maintenance:* At a lower dose adequate to maintain remission. *Adolescent and geriatric patient dose:* 25 to 50 mg. daily; increase to 100 mg. daily if necessary.

Overdosage: There is no specific antidote for desipramine, nor are there specific phenomena of diagnostic value characterizing poisoning by the drug. The principles of management of coma and shock by means of the mechanical respirator, cardiac pacemaker, monitoring of central venous pressure and regulation of fluid and acid-base balance are well known in most medical centers. If heart failure is imminent, digitalize promptly.

What can a long-acting injectable phenothiazine do that a short-acting oral can't?

It can save time, it can save money, and it can even save people – by reducing readmissions.

Time Prolixin Decanoate (Fluphenazine Decanoate Injection), with duration of action that may last up to 4 weeks or longer in patients on maintenance therapy, can effect important savings in nursing time.

Approximate Staff Time Required to Medicate 18 Schizophrenic Patients*

8 a.m. ¾ hr. 1 p.m. ¾ hr. 6 p.m. ¾ hr.	1 injection every 28 days for most patients
= 2¼ hours nursing time	4 minutes required for each injection
2¼ hrs. x 28 days = 63 hours of nursing time every 28 days	= 1 hr., 10 minutes nursing time in 28 days
NURSING TIME SAVED IN 28 DAYS	61 hours and 50 minutes or more than 7½ eight-hour working days

*Adapted from Platt R: Br J Social Psychiatry 2: 187-191, 1968.

Money Martin and Townend[1], who found from their study of Prolixin Decanoate that 15 of 39 patients could be maintained on 25 mg. every 4 weeks, also note that on this basis "a year's maintenance on chlorpromazine represents the order of 110 grams of phenothiazine as opposed to 0.33 gram of fluphenazine." Translating this into dollars shows the following potential hospital savings on the basis of patient population:

Agent and amount/year	Form	Cost/patient/year	Cost/500 patients/year
Chlorpromazine (SKF brand) 110 grams	8 oz. concentrate 100 mg./ml.†	$48.75*	$24,375
Prolixin Decanoate .33 grams	5 ml. vials 25 mg./ml.	23.17**	11,585
SAVINGS		$25.58 patient, year	$12,790 500 pts/yr.

* Calculated from prices published in 1975 Red Book.
** Calculated from Squibb 1975 price catalogue.
† With tablets, the annual cost is even greater.

People The controlled drug delivery system of Prolixin Decanoate helps get schizophrenic patients out of the hospital and helps them stay out. It promotes continuity of therapy—reducing outpatient drug defaulting from approximately 50% with oral medications according to one report[2] to about 16% according to another report[3].

It reduces the number and length of rehospitalizations. In one study of 103 patients maintained on injections of long-acting fluphenazines, total hospital readmissions for a year were cut from 191 to 50 and inpatient time from 8,713 days to 1,335 days[4].

It facilitates return to a productive life. A 12-month followup of 103 discharged patients revealed 77% in full-time employment or household duties and only 23% unemployed[4].

PROLIXIN DECANOATE®

(Fluphenazine Decanoate Injection)

may control schizophrenic symptoms for up to 4 weeks or longer in patients on maintenance therapy.

SQUIBB® "The Priceless Ingredient of every product is the honor and integrity of its maker." ™

For product brief summary see following page.

H425-001R

PROLIXIN DECANOATE®

(Fluphenazine Decanoate Injection)

may control schizophrenic symptoms for up to 4 weeks or longer in patients on maintenance therapy.

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg. fluphenazine decanoate per ml. in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia, liver damage or renal insufficiency, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility that severe adverse reactions may occur which require immediate medical attention. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functions and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. These include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, and hyperreflexia; most often these are reversible, but they may be persistent. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of antiparkinsonian drugs such as benztropine mesylate or intravenous Caffeine and Sodium Benzoate Injection U.S.P., and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may have to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection U.S.P. is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.

HOW SUPPLIED: 1 ml. Unimatic® single dose preassembled syringes and cartridge-needle units, and 5 ml. vials.

No default insurance

Tofranil-PM®
imipramine pamoate

Geigy

In depression

Daily Dosage Chart

1 h.s.

A major reason for drug defaulting is multiple daily dosage schedules.

Ayd* reports that 70 percent of patients default on a q.i.d. regimen; 60 percent on t.i.d.; 30 percent on b.i.d., and only 7 percent on a single daily dose.

A single daily capsule that provides a full day's medication would logically assure better therapeutic results.

Because one capsule lasts from bedtime to bedtime, Tofranil-PM may markedly reduce the probability of missed doses.

For single-dose therapy in depression when the dosage is established.

Please review the prescribing information summarized on the back of this page.

*Ayd, F.J., Jr. (Ed.): Int. Drug Ther. Newslett. 7(9/10):35-50 (Nov./Dec.) 1972.

Tofranil-PM®
imipramine pamoate

One capsule lasts from bedtime to bedtime.

Tofranil-PM® brand of imipramine pamoate
Tofranil® brand of imipramine hydrochloride USP

Indications: For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications: The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil, brand of imipramine hydrochloride, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings: *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of this drug, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

- patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
- patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
- hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
- patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
- patients receiving guanethidine or similar agents since imipramine may block the pharmacologic effects of these drugs.

Usage in Children: Pending evaluation of results from clinical trials in children, Tofranil, brand of imipramine hydrochloride, is not recommended for treatment of depression in patients under twelve years of age.

Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Since imipramine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as operating an automobile or machinery, the patient should be cautioned accordingly.

Precautions: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil, brand of imipramine hydrochloride, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil, brand of imipramine hydrochloride, may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine hydrochloride should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g., paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Avoid the use of preparations, such as decongestants and local anesthetics, which contain any sympathomimetic amine (e.g., adrenalin, noradrenalin), since it has been reported that tricyclic antidepressants can potentiate the effects of catecholamines.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Tofranil-PM®
imipramine pamoate

In depression

Daily Dosage Chart

1 h.s.

Geigy

Adverse Reactions: Note: Although the listing which follows includes a few adverse reactions which have not been reported with this specific drug, the pharmacological similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when imipramine is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue); drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea; peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: Lower dosages are recommended for elderly patients and adolescents. Lower dosages are also recommended for outpatients as compared to hospitalized patients who will be under close supervision. Dosage should be initiated with Tofranil, brand of imipramine hydrochloride, at a low level and increased gradually, noting carefully the clinical response and any evidence of intolerance. Following remission, maintenance medication may be required for a longer period of time, at the lowest dose that will maintain remission.

Once-a-day maintenance dosage can be provided with Tofranil-PM, brand of imipramine pamoate, capsules if this dosage has been established as explained above. This dose may be given at bedtime. For the occasional patient who manifests stimulation and insomnia with this dosage regimen, the capsules may be given in the morning.

Parenteral administration should be used only for starting therapy in patients unable or unwilling to use oral medication. The oral form should supplant the injectable as soon as possible.

How Supplied: Tofranil, brand of imipramine hydrochloride: Round tablets of 25 and 50 mg.; triangular tablets of 10 mg.; and ampuls, each containing 25 mg. in 2 cc. for I.M. administration.

Tofranil-PM, brand of imipramine pamoate: Capsules of 75, 100, 125 and 150 mg. (Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg. of imipramine hydrochloride.)

Printed in U.S.A. (B) 98-146-850-R (2/74)

Basic tool of Western psychiatry

Thorazine®

brand of chlorpromazine

Tablets: 25 mg. of the HCl

- 'Thorazine' controls psychotic symptoms
- Especially useful in agitated, violent or anxious schizophrenic patients
- Unsurpassed clinical experience
- 18 dosage forms and strengths

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings: Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudo-parkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg.; Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

Effective control of psychotic agitation

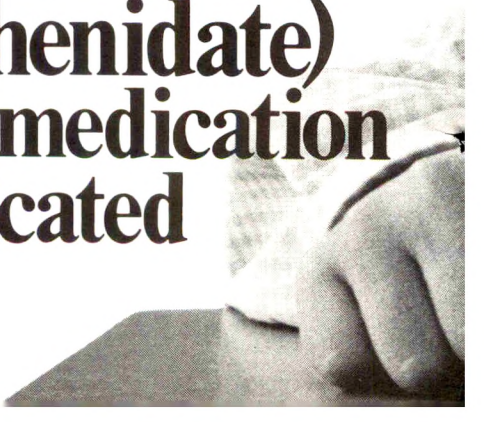
Tested by time and experience in

1962

"...a considerable decrease of hyperactivity...."[1]
Knobel, 1962

Over a decade of controlled studies and clinical experience has shown the effectiveness of Ritalin in reducing the hyperactivity,[1-3] distractibility,[1,4,5] and disorganized behavior[1-8] in the MBD child.

By lessening the effects of motor and attentional disorders, Ritalin can help the MBD child to better focus his attention on meaningful stimuli and thus can often improve cognition and promote learning.[6,9]

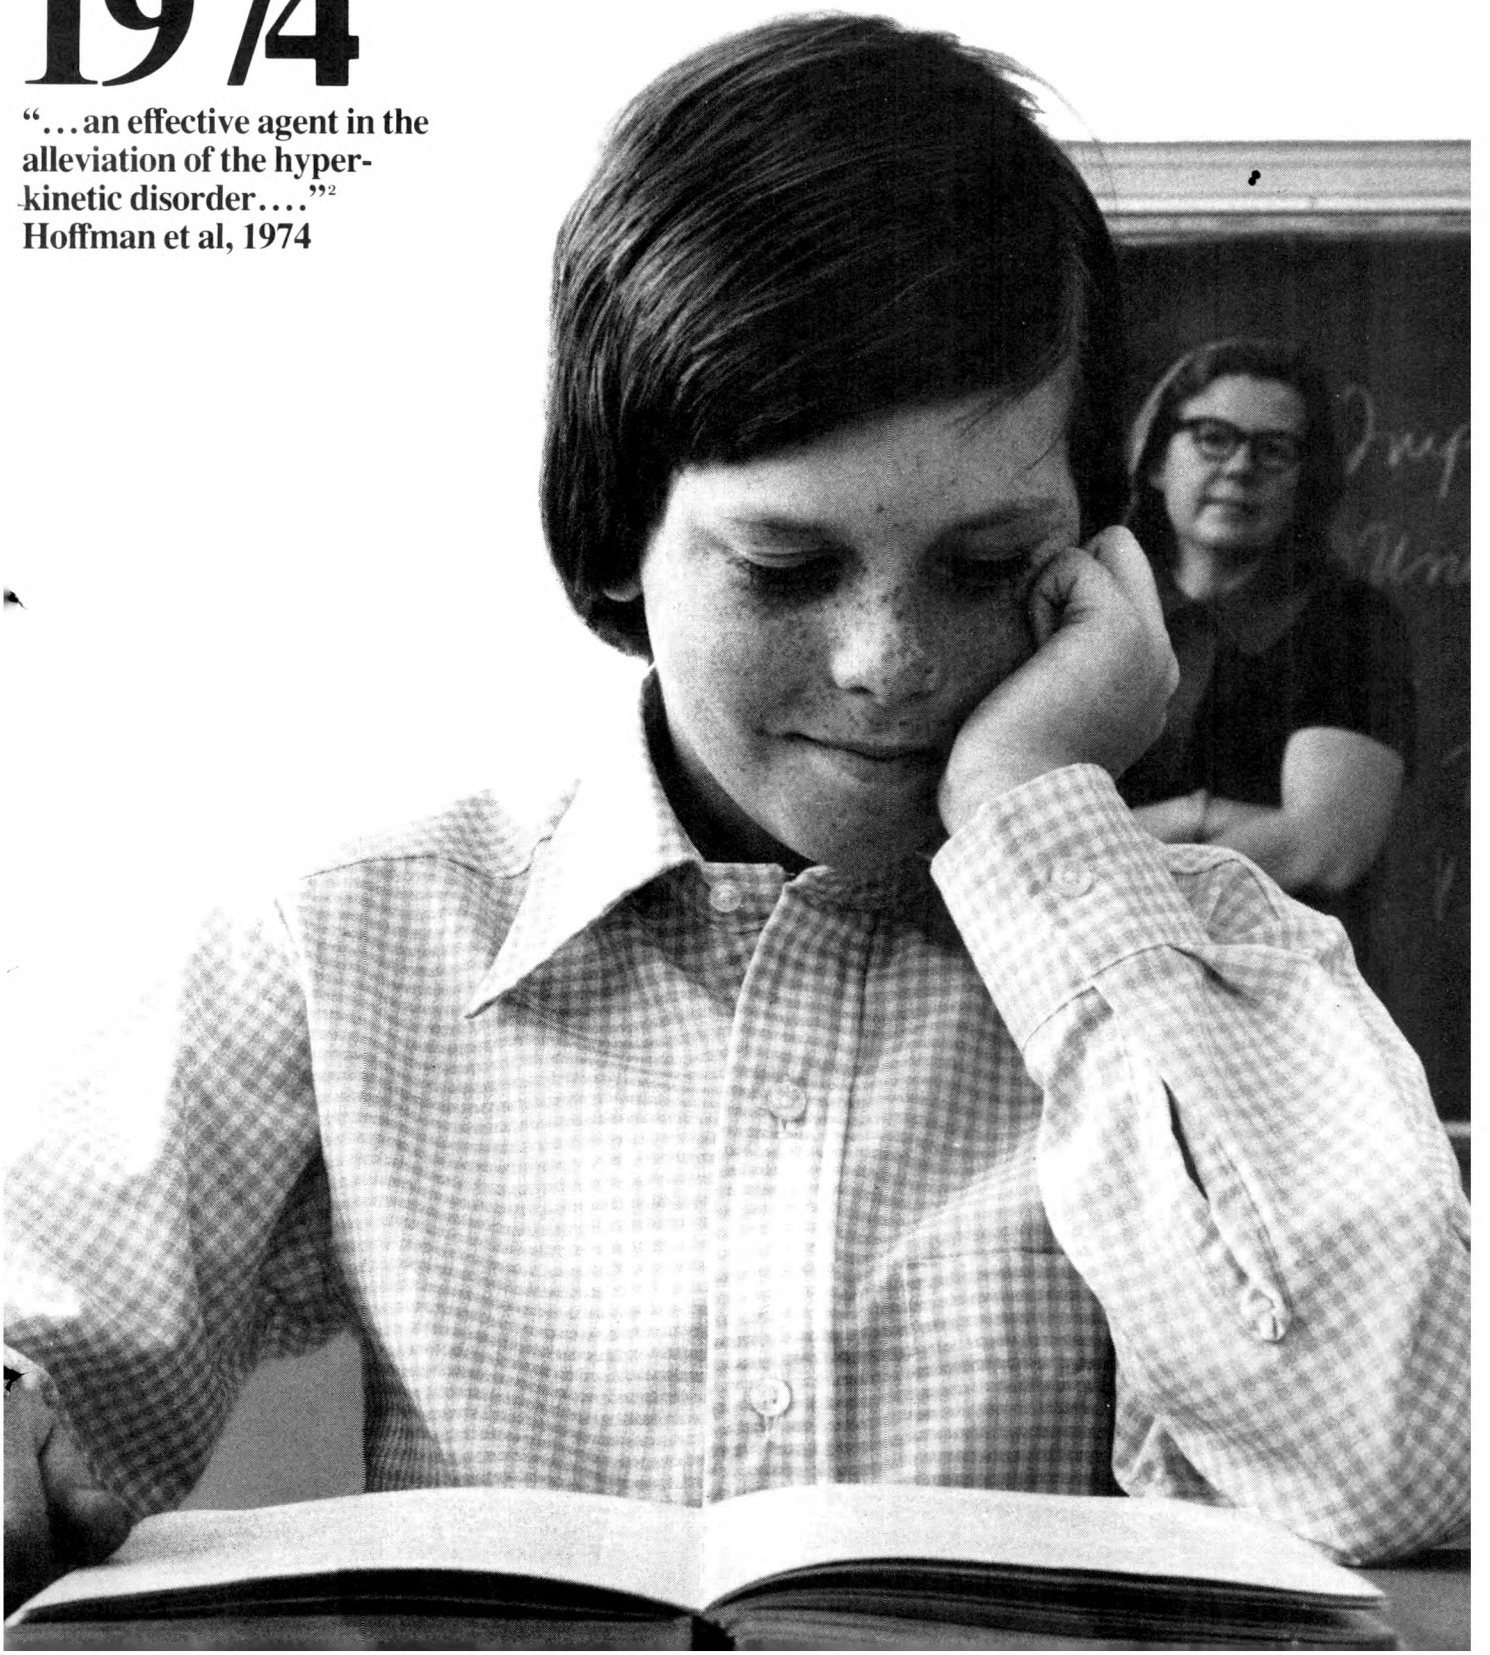


And side effects – insomnia and appetite loss – with Ritalin have occurred less frequently than with dextroamphetamine.[10,11]

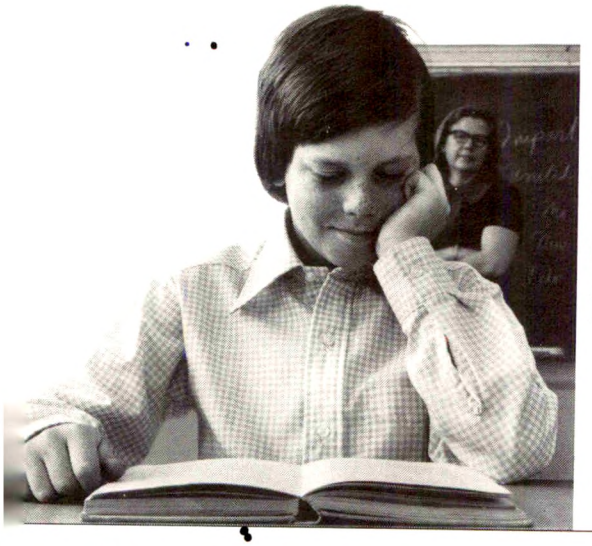
Indeed, Ritalin is currently a drug of choice in many MBD situations,[10,12] and can prove to be an important element in many complete remedial programs for MBD.

Therapy with Ritalin should be undertaken only after a medical diagnosis of MBD has been made. Drug treatment is not indicated for all children with MBD.

Dosage should be periodically interrupted. Often, these interruptions reveal some "stabilization" in the child's behavior even without medication, permitting a reduction in dosage and eventual discontinuance of drug therapy.



Ritalin®
(methylphenidate)
Only when medication is indicated



the treatment of MBD

TABLETS

INDICATION

Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)

Special Diagnostic Considerations

Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation, since Ritalin may aggravate these symptoms. Also contraindicated in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain and/or height) has been reported with long-term use of stimulants in children. Therefore, children requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin or for the prevention of normal fatigue states.

Ritalin may lower the convulsive threshold in patients with or without prior seizures; with or without prior EEG abnormalities, even in absence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. If seizures occur, Ritalin should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors. Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include: hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children with Minimal Brain Dysfunction (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500, and 1000.

Consult complete product literature before prescribing.

SEXUAL DYSFUNCTION: BEHAVIOR THERAPY WORKSHOPS

Small group intensive training workshops emphasizing therapy techniques for use by mental health professionals and physicians who deal with sexual complaints.

The following workshops will be offered: Progressive Relaxation; Systematic Desensitization; The Use of Films in Therapy; Sexual Attitude Reassessment; The Treatment of Male Sexual Dysfunction; The Treatment of Female Sexual Dysfunction; Taking a Behavioral Sex History; Facilitating Intimate Communication.

PHILADELPHIA, MARCH 5-6, 1976 — sponsored by the Behavior Therapy Unit, Department of Psychiatry, Temple University Medical School, Philadelphia, PA.

For information, please contact: Ms. B. J. Foster, Behavior Therapy Unit, Room 702, c/o E.P.P.I., Henry Avenue, Philadelphia, PA 19129. Phone (215) 438-4298.

The Princeton Center for Behavioral Consultation, in conjunction with local universities will sponsor this program in:

SAN FRANCISCO, MARCH 12-13, 1976
TORONTO, APRIL 9-10, 1976
NEW YORK, APRIL 23-24, 1976
DALLAS, MAY 8-9, 1976
HILTON HEAD, MAY 21-22, 1976

For information on these workshops, please contact: Ms. Debora Phillips, Princeton Center for Behavioral Consultation, Room 202, 53 Wilton Street, Princeton, NJ 08540.

PRINCE GEORGE REGIONAL HOSPITAL

The Prince George Regional Hospital is requesting applications from PSYCHIATRISTS. The hospital currently expanded to a 370 bed, (including a 27 bed Psychiatric Unit), fully accredited; active treatment Regional referral hospital, located in Central B.C., is situated in the City of Prince George. The present population of Prince George is approximately 70,000, and serves an area of about 150,000. Prince George is one of the fastest growing communities in the province and offers excellent educational and recreational facilities with easy access to Vancouver and other parts of Canada. Please direct enquiries to: Dr. P.J. Konkal, Chairman, Medical Manpower Committee, Prince George Regional Hospital, Prince George, B.C.

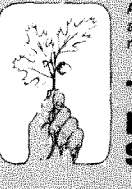
Three Treatment Centers

Three treatment centers provide individually prescribed programs of care, education, treatment and training for children, adolescents and adults with learning disabilities, neurological impairment, mental retardation or emotional disturbance.

Advantage: the availability of a large, trained and experienced staff, exchanging ideas and insights in a comprehensive program of supportive environment and individualized treatment.

Advantage: geographically separated to provide the proper residential milieu . . . yet near enough to benefit from the combined training and experience of a wide range of staff members.

The Oaks — A residential psychiatric treatment center for emotionally disturbed children and adolescents between the ages of six and 18. Co-educational, Austin. In addition, the Center provides a Short Term Adolescent Center and a six bed intensive care unit.



The San Marcos Treatment Center — a facility with three campuses designed for individuals with psychiatric, neurological, and intellectual difficulties who have evidenced a need for a 24-hour therapeutic milieu.

The Center offers a broad spectrum of services to both mentally retarded individuals and those with psychiatric disorders. In addition to a structured therapeutic environment, individual and group psychotherapy services are available to each resident. Clinical supervision and support services are provided by the Center psychiatrists.

The Ranch Treatment Center — located in the suburbs of Austin the Center provides both long-term and intermediate tenure services to multi-handicapped male adolescents and adults whose primary diagnostic classifications are in areas of mental retardation and mental illness. All residents receive program services which may permit their early discharge to the less restrictive settings of community-based programs.

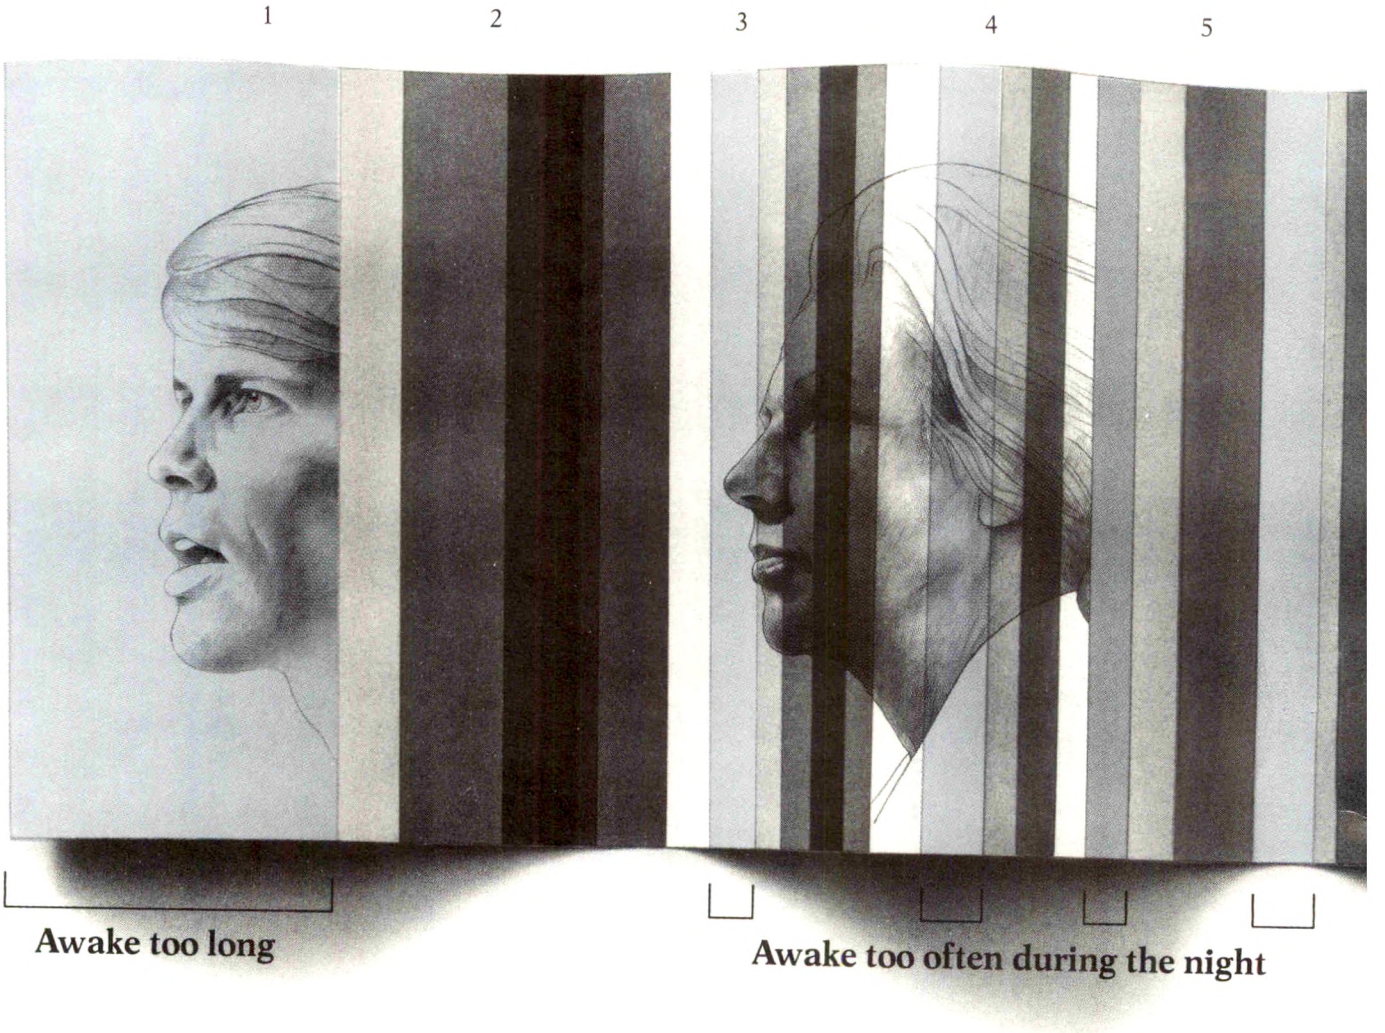
THE BROWN SCHOOLS

Effectiveness across the spectrum of most common forms of insomnia



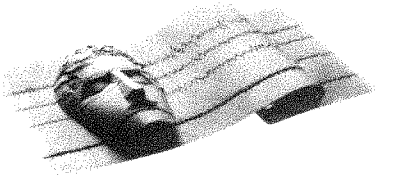
Awake too long, awake too often, awake too early...

These are the most common forms of insomnia, and may occur singly or in any combination. The night of troubled sleep depicted here comprises all three types. As the night progresses from left to right, each sleep stage is identifiable by its own shade of gray. Blue represents "Awake."

As you can see, this hypothetical "patient" takes well over an hour to fall asleep, awakens several times during the middle of the night and awakens too early in the morning.

Sleep Stages

- Awake
- REM
- Stage 1
- Stage 2
- Stage 3
- Stage 4



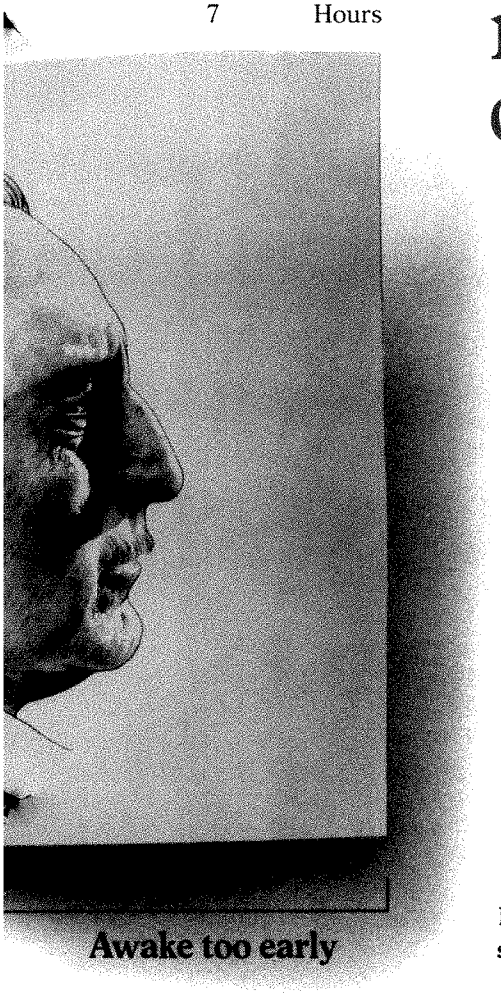
The insomnias most often occurring in young and older adults

For patients with trouble falling asleep (common in young adult insomnia patients), Dalmane (flurazepam HCl) 30 mg provides sleep within 17 minutes, on average. For those with trouble staying asleep or sleeping long enough (common in those over 50), Dalmane offers increased total sleep time with fewer nocturnal awakenings. These clinical results were demonstrated in studies conducted in four geographically separated sleep research laboratories[1-4]

The relative safety of Dalmane (flurazepam HCl) is well documented

Dalmane (flurazepam HCl) is relatively safe and well tolerated; morning "hang-over" has been infrequent. The usual adult dosage is 30 mg; in elderly or debilitated patients, limit initial dosage to 15 mg to preclude over-sedation, dizziness or ataxia. Caution patients about possible combined effects with alcohol and other CNS depressants.

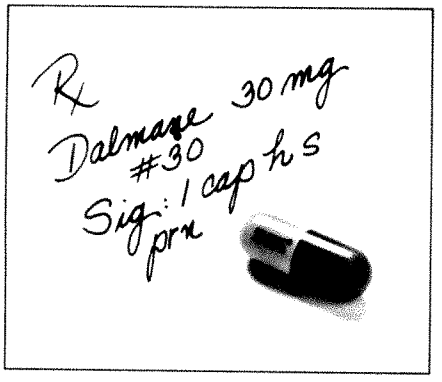
Broad-spectrum medication for the most common forms of insomnia



Dalmane®
(flurazepam HCl)

One 30-mg capsule *h.s.*— usual adult dosage
(15 mg may suffice in some patients).
One 15-mg capsule *h.s.*— initial dosage for elderly or debilitated patients.

- □ induces sleep rapidly
- □ reduces nighttime awakenings
- □ lengthens total sleep time



ROCHE

Please see following page for a summary of complete product information.

Broad-spectrum medication for the most common forms of insomnia

Dalmane®
(flurazepam HCl) ℞ IV

Objectively proved in the sleep research laboratory, Dalmane

- induces sleep within 17 minutes, on average
- reduces nighttime awakenings
- provides 7 to 8 hours sleep, on average, without repeating dosage

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:

Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; and in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.

Contraindications: Known hypersensitivity to flurazepam HCl.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Use in women who are or may become pregnant only when potential benefits have been weighed against possible hazards. Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.

Precautions: In elderly and debilitated, initial dosage should be limited to 15 mg to preclude oversedation, dizziness and/or ataxia. If combined with other drugs having hypnotic or CNS-depressant effects, consider potential additive effects. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.

Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported were headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase. Paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, have also been reported in rare instances.

Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until response is determined.

Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

Trilafon®

brand of
perphenazine, NF

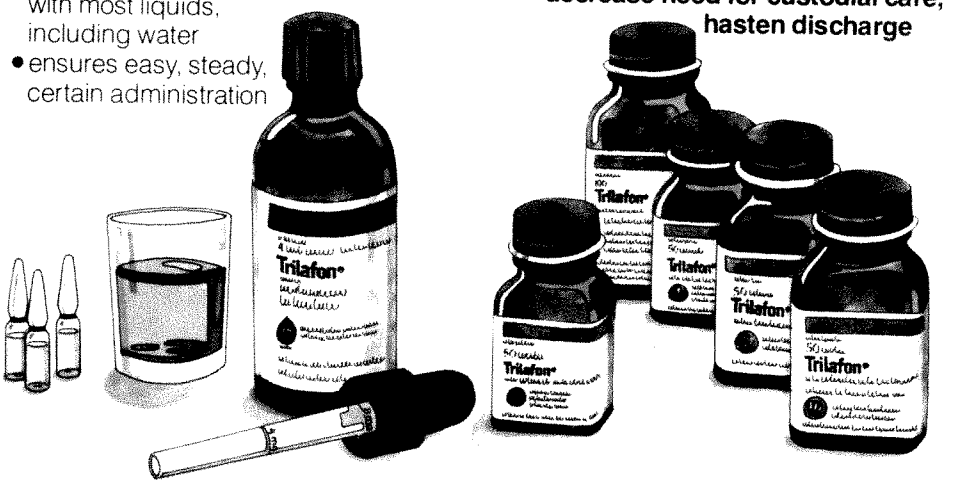
for the management of schizophrenic and manic disorders

- in the psychiatric hospital
- in the mental health clinic
- in out-patient treatment

INJECTION
when you want *emergency* control for *uncooperative* in-hospital patients



benefits
- usually takes effect in 10 minutes
- average duration of effect is 6 hours

CONCENTRATE
when you want *maintenance* control for *uncooperative* in-hospital patients

benefits
- tasteless, colorless, easily mixes with most liquids, including water
- ensures easy, steady, certain administration

TABLETS
when you want *maintenance* therapy for *cooperative* patients, in the hospital or at home

benefits
- **generally improve cooperation and communication**
- **decrease need for custodial care, hasten discharge**

Trilafon®
brand of perphenazine, NF
Tablets
REPETABS® Tablets
Concentrate
Injection

CONTRAINDICATIONS TRILAFON is contraindicated in drug-associated central nervous system depression (barbiturates, alcohol, narcotics, analgesics, antihistamines). Perphenazine is contraindicated in the presence of existing blood dyscrasias, bone marrow depression and pre-existing liver damage, and in patients who are hypersensitive to perphenazine.

TRILAFON **Injection** should not be given to patients in coma or severely depressed states.

WARNINGS **Usage in pregnancy:** Perphenazine should only be given to pregnant patients when, in the judgment of the physician, the potential benefits outweigh the possible risks.

Perphenazine can lower the convulsive threshold in susceptible individuals; it should be used with caution in patients with convulsive disorders. If the patient is being treated with an anticonvulsant agent, increased dosage of that agent may be required when perphenazine is used concomitantly.

Perphenazine should be used with caution in patients with psychic depression.

Perphenazine is not recommended for children under 12 years of age.

Perphenazine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as driving a car or operating machinery.

PRECAUTIONS As with any potent medication, patients receiving perphenazine should be under medical supervision, particularly if they are receiving high doses. Patients who have had any severe reaction to phenothiazines or to imipramine should be treated cautiously, under close medical supervision.

Although the following adverse reactions have not been reported in patients treated with perphenazine, the possibility that they might occur with TRILAFON should be considered: blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, eosinophilia); liver damage (biliary stasis); narrowing of the visual fields; pigmentation of the retina, cornea, or lens; cerebral edema; polyphagia; photophobia; hyperpyrexia.

If hypotension develops, levarterenol (norepinephrine) can be used, but not epinephrine, because epinephrine's action is blocked and partly reversed by perphenazine. Severe, acute hypotension has occurred with the use of phenothiazines and is of particular concern in patients with mitral insufficiency or pheochromocytoma.

A significant rise in body temperature may indicate an idiosyncratic reaction to perphenazine; treatment with perphenazine should be stopped if this occurs.

The antiemetic effect of perphenazine can obscure signs of toxicity due to overdosage of other drugs, or mask the symptoms of disease (eg, brain tumor or intestinal obstruction).

Contact dermatitis has been reported with a perphenazine solution; therefore, contact of hands or clothing by those handling perphenazine solutions should be avoided.

POTENTIATION Since phenothiazines can potentiate the central-nervous-system-depressant actions of opiates, antihistamines, barbiturates, and alcohol, less than the usual dosage of these agents is required when they are administered concomitantly with TRILAFON. Patients should be cautioned that their response to alcohol may be increased while they are being treated with TRILAFON.

Phenothiazines also potentiate the effects of atropine, heat, and phosphorus insecticides, and should be used with caution in persons exposed to these agents.

ADVERSE REACTIONS *Extrapyramidal reactions:* dystonia including protrusion, discoloration, aching and rounding of the tongue; tonic spasm of the masticatory muscles, tight feeling in the throat, slurred speech, dysphagia, oculogyric crisis, trismus, torticollis, retrocollis, muscle weakness, and aching and numbness of the limbs; akathisia; motor restlessness; dyskinesia, parkinsonism; hyperreflexia; and ataxia. The incidence and severity of these reactions usually increase with increased dosage, but have occurred in some patients receiving low dosage. Reduction in dosage or treatment with an antispasmodic agent will usually control extrapyramidal reactions. In some instances, however, these reactions may persist after discontinuation of treatment with perphenazine.

Persistent tardive dyskinesia: As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities. There is no known effective treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine, vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Allergic reactions: erythema, pruritus, urticaria, eczema, anaphylactoid reactions, and local and generalized edema. In extremely rare instances, individual idiosyncrasy or hypersensitivity to phenothiazines has resulted in cerebral edema, circulatory collapse, and death. Photosensitization, asthma, and exfoliative dermatitis have also occurred in patients treated with phenothiazines.

Autonomic reactions: blurred vision, dry mouth or salivation, nasal congestion, nausea, vomiting, hypertension, tachycardia, hypotension, anorexia, urinary frequency or incontinence, and constipation. Significant autonomic effects have been infrequent in patients receiving less than 24 mg. perphenazine daily.

Other reactions: endocrine disturbances (lactation, gynecomastia, galactorrhea, disturbances in the menstrual cycle), headaches, mild insomnia, altered cerebrospinal fluid proteins, ECG abnormalities, reactivation of psychosis, paradoxical excitement, paranoid-like reactions, catatonia, and systemic lupus erythematosus-like syndrome. Hypnotic effects appear to be minimal, particularly in patients who are permitted to remain active. The following adverse reactions, though rare, have also been reported to be associated with perphenazine treatment: agranulocytosis; jaundice; hyperpigmentation of the skin; grand mal convulsions; failure of ejaculation; hyperglycemia.

Side effects with intramuscular TRILAFON **Injection** have been infrequent and transient. Dizziness or significant hypotension after treatment with TRILAFON **Injection** is a rare occurrence.

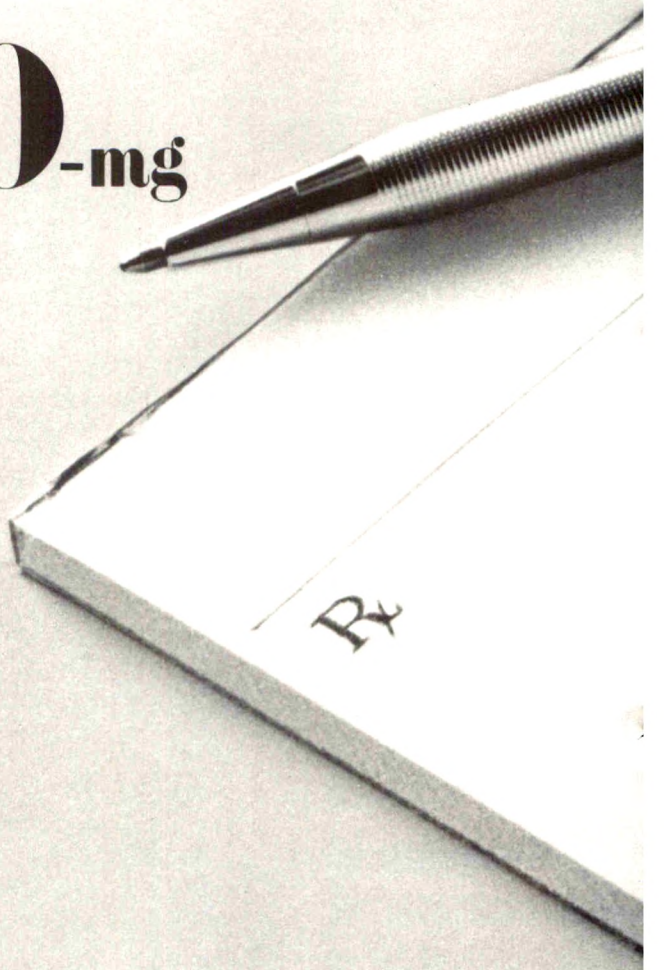
for clinically significant depression . . .

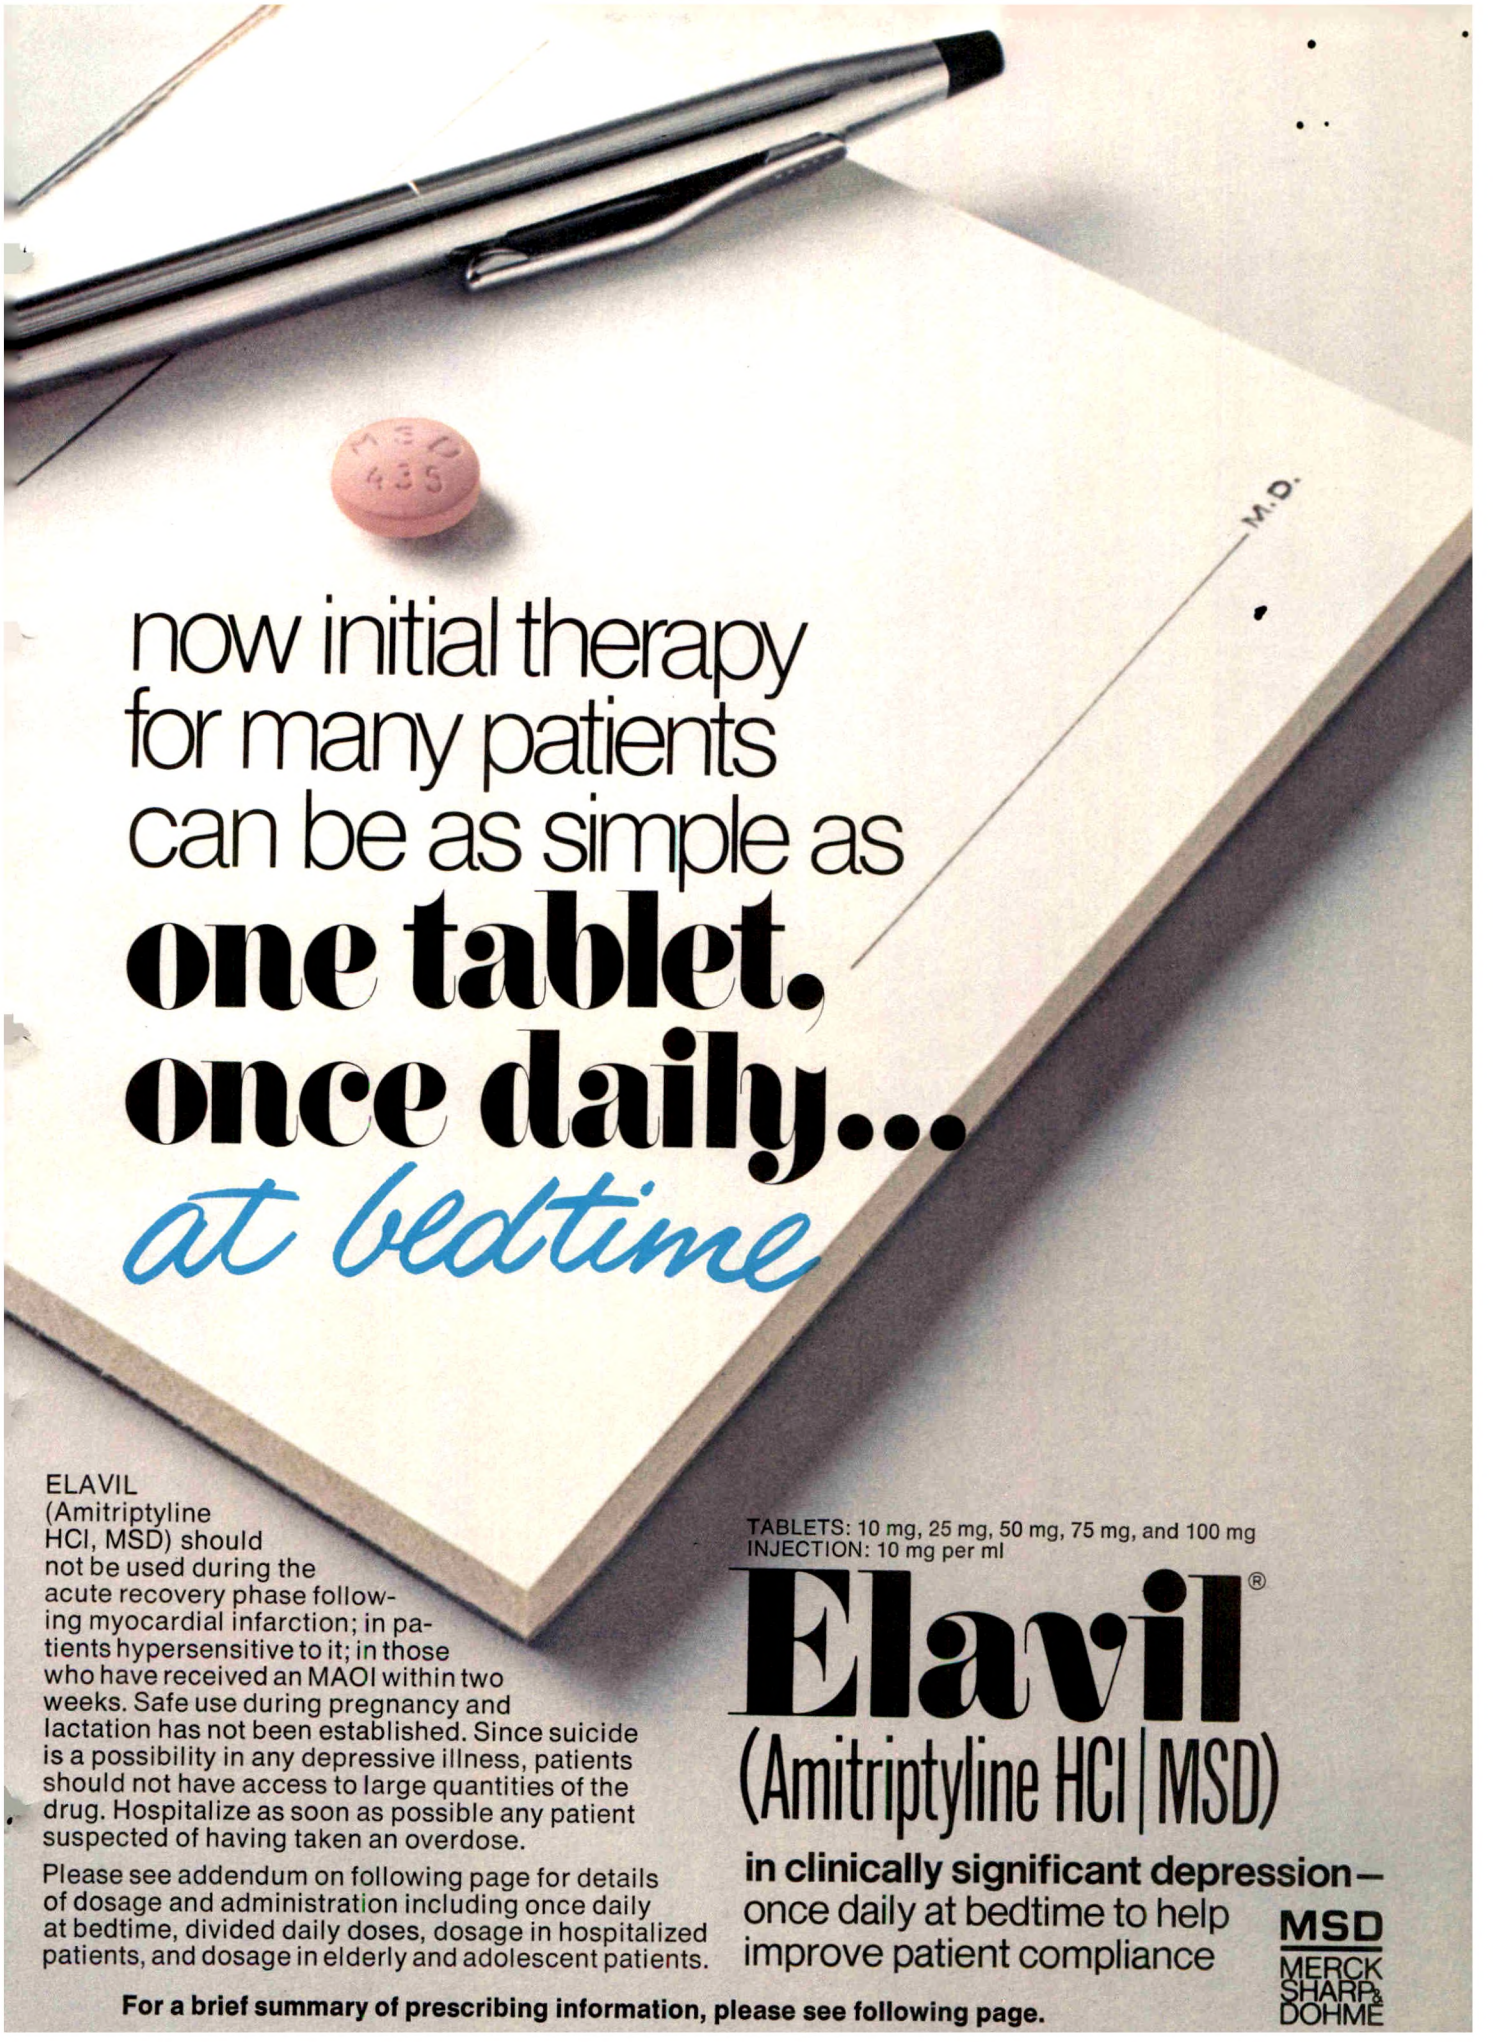
Merck Sharp & Dohme introduces

75- and 100-mg

TABLETS



Elavil®



(Amitriptyline HCl | MSD)

to further simplify once-daily

h.s.

therapy

now initial therapy for many patients can be as simple as **one tablet, once daily...** *at bedtime*

ELAVIL (Amitriptyline HCl, MSD) should not be used during the acute recovery phase following myocardial infarction; in patients hypersensitive to it; in those who have received an MAOI within two weeks. Safe use during pregnancy and lactation has not been established. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

Please see addendum on following page for details of dosage and administration including once daily at bedtime, divided daily doses, dosage in hospitalized patients, and dosage in elderly and adolescent patients.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg
INJECTION: 10 mg per ml

Elavil®
(Amitriptyline HCl | MSD)

in clinically significant depression— once daily at bedtime to help improve patient compliance

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please see following page.

NEW TABLETS

Elavil®

(Amitriptyline HCl | MSD)

75 mg and 100 mg

to further simplify once-daily

h.s.

therapy

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor or within at least 14 days following the discontinuance of a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have access to large quantities of the drug. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

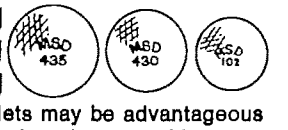
How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

addendum

MSD
MERCK SHARP & DOHME

Elavil®



(Amitriptyline HCl | MSD)

Five tablet strengths for differing patient needs. The variety of dosage strengths available with ELAVIL makes possible great prescribing flexibility.

Once-a-day dosage at bedtime is an appropriate way to start—and maintain—many patients on therapy. The simplicity of this regimen helps improve patient compliance. ELAVIL may also be prescribed in divided daily doses.

A sedative effect may be apparent before the antidepressant effect of ELAVIL is noted. An adequate therapeutic effect may take as long as 30 days to develop.

100 mg
75 mg
50 mg

These tablets may be advantageous when initiating therapy with once-daily bedtime dosage in adult outpatients. The usual starting dosage is 75 mg daily. Therapy may be initiated with 50 to 100 mg daily. This may be increased by 25 or 50 mg as necessary in the bedtime dose to a total of 150 mg per day.

These tablets may also be convenient for many hospitalized patients. These patients may need 100 mg a day initially which can be increased gradually to 200 mg a day if necessary. A small number of such patients may need as much as 300 mg a day.

25 mg

This tablet may prove useful when initiating therapy with divided daily doses in adult outpatients. Starting dosage is usually 75 mg daily. If necessary, this dosage may be increased gradually to a total of 150 mg a day. Increases are made preferably in the late afternoon or bedtime doses.

10 mg

Because lower doses are generally recommended for adolescents and elderly patients, the 10-mg tablets may be most serviceable. Ten mg three times a day with 20 mg at bedtime may be satisfactory in adolescent and elderly patients who do not tolerate higher doses.

NOTE: The usual maintenance dosage of ELAVIL is 50 to 100 mg per day which may be given in a single dose preferably at bedtime. In some patients 40 mg per day is sufficient. This drug is not recommended for patients under 12 years of age.

CHARLES C THOMAS • PUBLISHER

BECOMING A PSYCHOTHERAPIST *by* **Jacquelin Goldman,** *Univ. of Florida, Gainesville.* This introduction to psychotherapy is designed to be useful for students in clinical and counseling psychology, psychiatry, social work, psychiatric nursing and in counseling education programs. The student therapist learns to recognize behavior patterns, to formulate the meaning of behavior, and to understand how his own behavior and that of the patient relate to effective intervention. *'76, 140 pp., 2 il., $9.50*

BEHAVIORAL SCIENCE IN CLINICAL MEDICINE *by* **Stewart Wolf,** *Univ. of Texas Medical Branch, Galveston, Texas, and* **Helen Goodell,** *Cornell-New York Hospital Medical Center, New York.* Health and well-being depend not only on man's capacity to adapt to the tangible environment, but also to prevailing attitudes and values in his society and to his own goals and aspirations. The author discusses behavioral science in the context of human ecology, man's needs and expectations, the significance of medical education, the cultivation of the individual and its significance in the practice of medicine, and values and fulfillment. *'76, 256 pp., 22 il., $14.50*

LEGACIES IN THE STUDY OF BEHAVIOR: The Wisdom and Experience of Many *edited by* **Joseph Warren Cullen,** *National Institutes of Health, Bethesda, Maryland. (With 11 Contributors)* Presented here is a series of essays written by internationally known figures on issues which they feel are of mutual interest to the scientific community in general and behavioralists in particular. Some of the ideas presented include the physiologist at work, personality as an integrative concept in psychology, the study of behavior, exploring with drugs, medical research in a federal agency, how to do basic medical research and man's nonphysical nature. *'75, 288 pp., 38 il., $17.50*

LIVING OR DYING: Adaptation to Hemodialysis *edited by* **Norman B. Levy,** *State Univ. of New York, Brooklyn. (13 Contributors)* This book, the first devoted to the psychological aspects of hemodialysis, presents studies by leading authorities on the major problems in psychological adaptation to this procedure. Included are the special psychiatric problems of the child receiving hemodialysis, the uncooperative hemodialysis patient, psychological factors determining survival, and changes in sexual activity. *'74, 164 pp., 34 tables, $10.75*

PSYCHOLOGICAL ASSESSMENT OF SUICIDAL RISK *edited by* **Charles Neuringer,** *Univ. of Kansas, Lawrence. (15 Contributors)* Developed by experts in the field, this volume provides a history and evaluation of suicidal risk measurement and its validity. Three general approaches are discussed: one based on behavioral and demographic lethality scales, another involving assessment with psychological tests, and the third approach utilizing results of survey research of suicidal characteristics. Chapters in this book are original contributions and represent the latest work in suicidal risk assessment. *'74, 256 pp., 3 il., 33 tables, $11.75*

THE HAND TEST: A New Projective Test with Special Reference to the Prediction of Overt Aggressive Behavior (4th Ptg.) *by* **Barry Bricklin** *and* **Zygmunt A. Piotrowski,** *both of Jefferson Medical College, Philadelphia, Pennsylvania, and* **Edwin E. Wagner,** *Univ. of Akron, Akron, Ohio.* New projective personality testing is described which predicts potentially aggressive behavior and other facets of interpersonal behavior. *'75, 116 pp. (5 3/4 x 8 3/4), $6.50*

THE DIAGNOSIS AND TREATMENT OF ALCOHOLISM *by* **Gary G. Forrest,** *Department of Psychiatry, Department of the Army, Fort Carson, Colorado.* Essential tools for understanding, diagnosing and treating individuals experiencing significant interpersonal and social difficulty as a result of their drinking are provided in this text. The essentials of the addictive process are discussed and treatment and rehabilitation strategies are examined. The final section of clinical readings covers a wealth of practical, specific issues of psychotherapy, rehabilitation and research in the area of alcoholism. All personnel involved in the delivery of alcohol rehabilitation services will find this text an important resource. *'75, 272 pp., 6 tables, cloth-$12.75, paper-$8.95*

NEW TREATMENT APPROACHES TO JUVENILE DELINQUENCY *edited by* **J. L. Khanna,** *Univ. of Tennessee College of Medicine, Memphis. (16 Contributors)* The ideas presented reflect the latest positions held by eminent contributors selected from the fields of psychology, psychiatry, criminology and law. These papers range from a national perspective on juvenile delinquency to a description and discussion of nationally known treatment models as represented by the Janus House for Delinquents, the Achievement Place Model, the Florida Juvenile Rehabilitation Project, Project ACE and the contingency management of delinquent behavior in the community. *'75, 164 pp., 9 il., 12 tables, $11.75*

SEX EDUCATION AND COUNSELING OF SPECIAL GROUPS: The Mentally and Physically Handicapped, Ill, Elderly and Others *by* **Warren R. Johnson,** *Univ. of Maryland, College Park.* Some topics discussed are the nature of special groups and their sexuality; possible approaches to the sexuality of special groups; the nature of sexual normality; the danger of losing individuals behind group labels; and precautions to be observed in sex education and counseling. *'75, 224 pp., $12.50*

GROUP PROCESS TODAY: Evaluation and Perspective *compiled and edited by* **Donald S. Milman** *and* **George D. Goldman,** *both of Adelphi Univ., Garden City, New York. (20 Contributors)* Written by many of the foremost authorities in their respective areas in this country, this book is a comprehensive survey of what is going on in group process and group psychotherapy today. Originating from a psychoanalytic training program's conference, it is broad-based, combining the theoretical and the applied, with papers written in a clear and very readable style. *'74, 336 pp., 2 tables, $14.75*

'STELAZINE' PROVIDES EFFECTIVE CONTROL OF HALLUCINATIONS, DELUSIONS, ANXIETY AND OTHER PSYCHOTIC SYMPTOMS.
BECAUSE IT APPEARS TO HAVE AN ACTIVATING EFFECT, 'STELAZINE' IS ESPECIALLY USEFUL IN WITHDRAWN, APATHETIC OR DETACHED PATIENTS.

- CONTROLS PSYCHOTIC SYMPTOMS
- SELDOM CAUSES EXCESSIVE SEDATION
- CONVENIENT B.I.D. DOSAGE

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F Co.) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only) 10 mg./ml.

OXFORD

Criminality and Psychiatric Disorders

SAMUEL B. GUZE, Washington University School of Medicine. This book reviews a series of studies begun by Dr. Guze and his colleagues in 1959 that probably represents the most extensive and systematic long-term psychiatric study of criminals ever made. Two hundred ninety-nine felons of both sexes were studied with the cooperation of the Missouri Board of Probation and Parole. Sociopathy, alcoholism and drug dependence were found to be the psychiatric disorders characteristically associated with serious crime.

1976 176 pp. $9.50

Malnutrition and Brain Development

MYRON WINICK, Columbia University College of Physicians and Surgeons. This book explores the relationship between malnutrition in early life and retarded brain development. The author gives an overview of clinical malnutrition and then describes the biochemical changes that occur in the developing nervous system, the effects of undernutrition on these changes, the possible damage that prenatal malnutrition may have on a fetus, and the effects of early malnutrition on mental development.

1976 176 pp. 59 illus. $9.95

Explaining the Brain

W. RITCHIE RUSSELL, University of Oxford, with A. J. Dewar. This clear and readable account of the brain treats memory, pain, nerve cells, the infant brain and its development, concentration and thinking, phantom limbs and psychosomatic disease, concussion, brain damage, and the effects of drugs. The emphasis is on the learning process, and the way in which the brain functions.

1975 200 pp. 23 illus. cloth $11.50 paper $4.00

Neuropsychological Assessment

MURIEL D. LEZAK, University of Oregon Medical School. A comprehensive source-book on adult neuropsychology, this volume combines a clear and well-documented exposition of the brain-behavior relationships underlying higher mental activity with a practical guide to neuropsychological testing. It provides the material for wide-ranging and in-depth clinical examination of the higher mental functions in a detailed review of some 200 psychological tests and assessment techniques used for neuropsychological evaluation.

July 1976 500 pp. 62 illus. $15.00

Prices and publication dates are subject to change.

Society, Stress, and Disease

Volume 2: Childhood and Adolescence

Edited by LENNART LEVI, Karolinska Institute, Sweden. During this century new physical and psychosocial stresses have emerged, associated with the changing patterns of family and community life. Their effects on the formative years of childhood and adolescence are of particular importance. This volume presents papers and discussions concerned with the stressors which influence development during this time, and considers practical ways of applying existing scientific knowledge in the prevention and alleviation of disorders.

1976 560 pp. $67.50

Psychiatric Diagnosis

ROBERT A. WOODRUFF, DONALD W. GOODWIN, and SAMUEL B. GUZE, all of Washington University School of Medicine. "This well-researched and well-organized book deals in some detail with the various diagnostic entities seen in the clinical practice of psychiatry. . . . Statements are well documented with references to the psychiatric literature, and the bibliography at the end of each chapter is extensive." — Peter M. Zeman in *The American Journal of Psychiatry*

1974 224 pp. illus. cloth $7.95 paper $4.95

A Handbook for the Study of Suicide

Edited by SEYMOUR PERLIN, Georgetown University and George Washington University School of Medicine. A balanced psychiatric consideration of suicidal behavior, this book presents a wide range of information gathered from several disciplines. "This volume will be a very useful addition to the library of medical students and doctoral students in social science. It should also have a place on the reading list of every psychiatric resident." — Marvin Stern in *The American Journal of Psychiatry*

1975 272 pp. 9 illus. cloth $9.95 paper $5.95

Is Alcoholism Hereditary?

DONALD W. GOODWIN, Washington University School of Medicine. Alcoholism runs in families, but it is not clear whether this can be explained on a genetic or environmental basis. This book presents the evidence on both sides, reviewing a wide variety of viewpoints and scientific studies. In presenting the genetic view, the text focuses on an adoption study performed by the author and his colleagues in Denmark, which represents the strongest available evidence that alcoholism is genetically determined. The effects of alcohol within the body are also described and a detailed clinical picture of alcoholism is given.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in duplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit two copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

Communications about a manuscript, by letter or telephone (202-232-7878), should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; in the case of other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, which is a copyrighted publication, the legal ownership of all parts of the paper, including any illustrations, passes from the author to the *Journal*. If an individual or organization wishes to reprint material published in the *Journal*, written permission must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Wash., D.C. 20009; there will usually be a charge for granting this permission.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not reflect the official attitude or position of the American Psychiatric Association or of the *Journal's* Editorial Board.

SPECIFICATIONS FOR MANUSCRIPTS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond (or other opaque) paper. All parts of the manuscript (including case reports, footnotes, references, etc.) should be double-spaced, with generous margins. Subheads should be inserted at reasonable intervals to aid in comprehension and to break the typographical monotony of lengthy texts. Abbreviations not easily recognized by the average reader should be explained.

Length. As a general rule the manuscript of a regular article should not exceed 10–12 typed pages, unless a special arrangement has been made with the Editor; Brief Communications should not exceed eight typed pages. Letters to the Editor should not exceed 500 words unless a special arrangement has been made with the Editor.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the co-author who has been designated to handle the galley proofs and reprint requests. The number of authors should preferably not exceed four, with other collaborators being acknowledged in a footnote.

Precis. A brief precis is included at the beginning of each article: 60–100 words for regular articles, 40–60 words for Brief Communications. The author may prepare the precis himself or ask that the *Journal* staff prepare it, in which case the author may make any necessary changes on the galley proofs.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

References. References should be typed double-spaced on a separate sheet of paper, to be attached at the end of the manuscript. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below for books and journal articles; chapters in books will be treated as journal articles with regard to capitalization. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Titles and headings of any tables and figures should be sufficiently clear that the meaning of the data is understandable without reference to the text. See recent issues of the *Journal* for the general requirements of style.

Each table should be typed on a separate sheet, attached at the end of the manuscript. The data should be arranged so that columns of like material read down, not across.

A complete set of figures, preferably in the form of glossy prints, should accompany each of the two copies of the manuscript. Most figures will be reduced to about 3¼ inches in width, the column width of the *Journal*; all elements of a figure should be prepared to withstand this reduction. Graphs should be finished drawings not requiring further artwork. Authors are urged to engage the services of a professional in the preparation of figures. Authors may be required to meet the costs of any further artwork that must be done in the editorial office.

AUTHORS' CORRECTIONS

Galley proofs will be sent to the first-named author for corrections after the paper has been scheduled for publication; prompt return (preferably within 48 hours of receipt) is necessary to ensure publication in the assigned month. If an author expects to be away from his office for a long period of time after he has received the acceptance letter, he should inform the *Journal* office or arrange with a colleague to read the proofs. Authors are urged to keep changes on galleys to a minimum.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be attached to the galley proofs submitted to authors for correction. Reprints are usually mailed to authors about a month after publication of the article. Requests from others to order reprints should be directed to the Editor; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

Released from symptoms of psychotic depression...

Productive again.

By helping to reduce the frequency and intensity of psychotic symptoms, Navane (thiothixene) often permits resumption of more normal, more productive living.

The antipsychotic effectiveness of Navane—with relatively little drowsiness—helps patients remain more active, more alert, better able to meet the ordinary demands of life.

Cardiovascular side effects such as hypotension and nonspecific EKG changes are relatively rare with Navane (thiothixene). Extrapyramidal symptoms have been reported, but are usually controlled by reduction in dosage and/or administration of antiparkinson drugs.

Once you've controlled acute psychosis or psychotic depression, some patients can be maintained on a simple once-a-day dose. This once-a-day regimen can reduce the risk of missed doses with no loss of efficacy.

Navane®

(thiothixene) (thiothixene hydrochloride)

Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg/Concentrate 5 mg/ml

Once-a-day–to help control symptoms of psychosis

For prescribing information, including adverse reactions and contraindications please see following page of this advertisement.

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Actions. Navane is a psychotropic agent of the thioxanthene series. Navane possesses certain chemical and pharmacological similarities to the piperazine phenothiazines and differences from the aliphatic group of phenothiazines. Navane's mode of action has not been clearly established.

Indications. Navane is effective in the management of manifestations of psychotic disorders.

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy* – Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children–The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration – As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane. Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudoparkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leucocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate–In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor elevating action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg. of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

Three Treatment Centers

Three treatment centers provide individually prescribed programs of care, education, treatment and training for children, adolescents and adults with learning disabilities, neurological impairment, mental retardation or emotional disturbance.

Advantage: the availability of a **large, trained and experienced staff,** exchanging ideas and insights in a comprehensive program of supportive environment and individualized treatment.

Advantage: **geographically separated** to provide the proper residential milieu . . . yet near enough to benefit from the combined training and experience of a wide range of staff members.

The Oaks — A residential psychiatric treatment center for emotionally disturbed children and adolescents between the ages of six and 18. Coeducational, Austin. In addition, the Center provides a Short Term Adolescent Center and a six bed intensive care unit.

The San Marcos Treatment Center — a facility with three campuses designed for individuals with psychiatric, neurological, and intellectual difficulties who have evidenced a need for a 24-hour therapeutic milieu.

The Center offers a broad spectrum of services to both mentally retarded individuals and those with psychiatric disorders. In addition to a structured therapeutic environment, individual and group psychotherapy services are available to each resident. Clinical supervision and support services are provided by the Center psychiatrists.

The Ranch Treatment Center — located in the suburbs of Austin the Center provides both long-term and intermediate tenure services to multi-handicapped male adolescents and adults whose primary diagnostic classifications are in areas of mental retardation and mental illness. All residents receive program services which may permit their early discharge to the less restrictive settings of community-based programs.

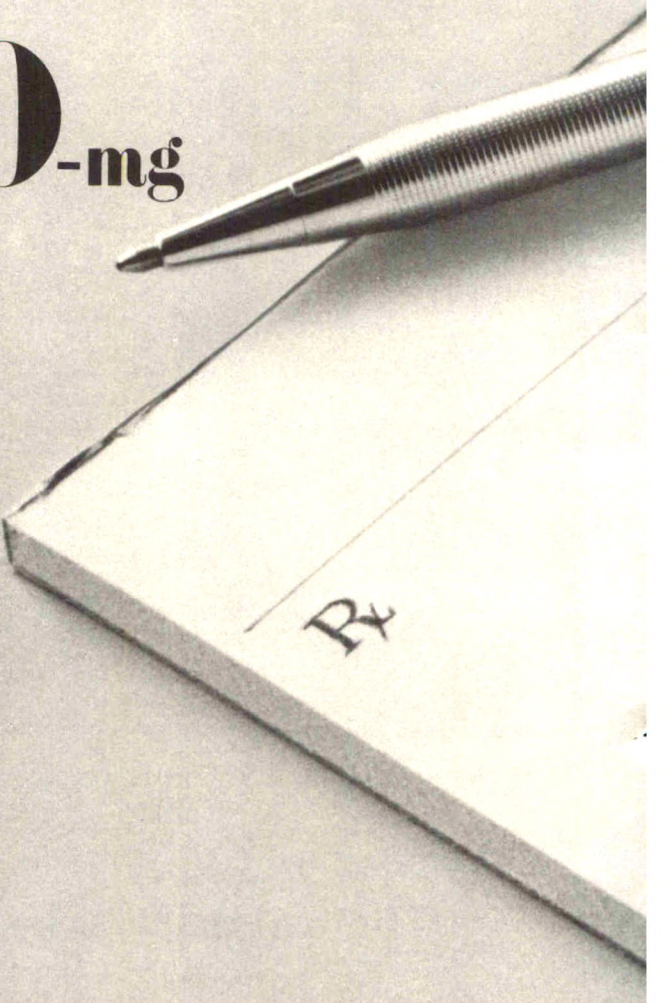
Merck Sharp & Dohme introduces

75- and 100-mg

TABLETS



Elavil®

(Amitriptyline HCl | MSD)

to further simplify once-daily

h.s.

therapy

now initial therapy for many patients can be as simple as **one tablet, once daily...** *at bedtime*

ELAVIL (Amitriptyline HCl, MSD) should not be used during the acute recovery phase following myocardial infarction; in patients hypersensitive to it; in those who have received an MAOI within two weeks. Safe use during pregnancy and lactation has not been established. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

Please see addendum on following page for details of dosage and administration including once daily at bedtime, divided daily doses, dosage in hospitalized patients, and dosage in elderly and adolescent patients.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, and 100 mg
INJECTION: 10 mg per ml

Elavil®
(Amitriptyline HCl | MSD)

in clinically significant depression— once daily at bedtime to help improve patient compliance

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please see following page.

NEW TABLETS

Elavil®

(Amitriptyline HCl | MSD)

75 mg and 100 mg

to further simplify once-daily

h.s.

therapy

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor or within at least 14 days following the discontinuance of a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have access to large quantities of the drug. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

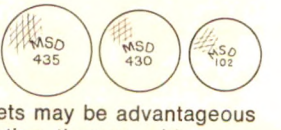
How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

addendum

MSD
MERCK SHARP & DOHME

Elavil®



(Amitriptyline HCl | MSD)

Five tablet strengths for differing patient needs. The variety of dosage strengths available with ELAVIL makes possible great prescribing flexibility.

Once-a-day dosage at bedtime is an appropriate way to start—and maintain—many patients on therapy. The simplicity of this regimen helps improve patient compliance. ELAVIL may also be prescribed in divided daily doses.

A sedative effect may be apparent before the antidepressant effect of ELAVIL is noted. An adequate therapeutic effect may take as long as 30 days to develop.

100 mg
75 mg
50 mg

These tablets may be advantageous when initiating therapy with once-daily bedtime dosage in adult outpatients. The usual starting dosage is 75 mg daily. Therapy may be initiated with 50 to 100 mg daily. This may be increased by 25 or 50 mg as necessary in the bedtime dose to a total of 150 mg per day.

These tablets may also be convenient for many hospitalized patients. These patients may need 100 mg a day initially which can be increased gradually to 200 mg a day if necessary. A small number of such patients may need as much as 300 mg a day.

25 mg

This tablet may prove useful when initiating therapy with divided daily doses in adult outpatients. Starting dosage is usually 75 mg daily. If necessary, this dosage may be increased gradually to a total of 150 mg a day. Increases are made preferably in the late afternoon or bedtime doses.

10 mg

Because lower doses are generally recommended for adolescents and elderly patients, the 10-mg tablets may be most serviceable. Ten mg three times a day with 20 mg at bedtime may be satisfactory in adolescent and elderly patients who do not tolerate higher doses.

NOTE: The usual maintenance dosage of ELAVIL is 50 to 100 mg per day which may be given in a single dose preferably at bedtime. In some patients 40 mg per day is sufficient. This drug is not recommended for patients under 12 years of age.

Coverage and Utilization of Care for Mental Conditions Under Health Insurance —Various Studies, 1973–74

By Louis S. Reed, Ph.D.
Consultant in Health Economics, American Psychiatric Association

This book reports six studies that add to the growing body of data demonstrating the feasibility of covering mental illness under health insurance. Although in some ways it may be considered a supplement to APA's 1972 book **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (Reed, Myers, and Scheidemandel), all of the data are new. The studies cover the following areas:

- Utilization of mental benefits under the Blue Cross and Blue Shield plan for federal employees, documenting that a "plateau" in the use of these benefits was reached in 1973–74.
- Comparison of benefits for mental and other illnesses under selected employee health benefit plans.
- Coverage of mental illness under collective bargaining agreements of selected unions.
- Utilization of care for mental conditions under the Canadian health insurance program, which gives the same coverage for mental as for other conditions.
- Updating of information on Blue Cross benefits for hospital care of mental illness.
- Data from selected Blue Cross and Blue Shield plans on coverage and utilization of mental conditions, with emphasis on major medical coverage.

80pp. Paperbound

Single copy, $4.00; 10–49 copies; $3.80 each; 50 or more copies, $3.20 each.

SPECIAL OFFER: One copy of this book (regular price, $4.00) and one copy of **HEALTH INSURANCE AND PSYCHIATRIC CARE: UTILIZATION AND COST** (regular price, $6.50) for $8.50.

W.. t.. c.. n .. lo..g- .cti..g injectable phenothiazine do that a short-acting oral can't?

It can save time, it can save money, and it can even save people – by reducing readmissions.

Time Prolixin Decanoate (Fluphenazine Decanoate Injection), with duration of action that may last up to 4 weeks or longer in patients on maintenance therapy, can effect important savings in nursing time.

Approximate Staff Time Required to Medicate 18 Schizophrenic Patients*

8 a.m. ¾ hr. 1 p.m. ¾ hr. 6 p.m. ¾ hr.	1 injection every 28 days for most patients
= 2¼ hours nursing time	4 minutes required for each injection
2¼ hrs. x 28 days = 63 hours of nursing time every 28 days	= 1 hr., 10 minutes nursing time in 28 days
NURSING TIME SAVED IN 28 DAYS	61 hours and 50 minutes or more than 7½ eight-hour working days

*Adapted from Platt R: Br J Social Psychiatry 2: 187-191, 1968.

Money Martin and Townend[1], who found from their study of Prolixin Decanoate that 15 of 39 patients could be maintained on 25 mg. every 4 weeks, also note that on this basis "a year's maintenance on chlorpromazine represents the order of 110 grams of phenothiazine as opposed to 0.33 gram of fluphenazine." Translating this into dollars shows the following potential hospital savings on the basis of patient population:

Agent and amount/year	Form	Cost/patient/year	Cost/500 patients/year
Chlorpromazine (SKF brand) 110 grams	8 oz. concentrate 100 mg./ml.†	$48.75*	$24,375
Prolixin Decanoate .33 grams	5 ml. vials 25 mg./ml.	23.17**	11,585
SAVINGS		$25.58 patient, year	$12,790 500 pts/yr.

* Calculated from prices published in 1975 Red Book.
** Calculated from Squibb 1975 price catalogue.
† With tablets, the annual cost is even greater.

People The controlled drug delivery system of Prolixin Decanoate helps get schizophrenic patients out of the hospital and helps them stay out. It promotes continuity of therapy—reducing outpatient drug defaulting from approximately 50% with oral medications according to one report[2] to about 16% according to another report[3].

It reduces the number and length of rehospitalizations. In one study of 103 patients maintained on injections of long-acting fluphenazines, total hospital readmissions for a year were cut from 191 to 50 and inpatient time from 8,713 days to 1,335 days[4].

It facilitates return to a productive life. A 12-month followup of 103 discharged patients revealed 77% in full-time employment or household duties and only 23% unemployed[4].

PROLIXIN DECANOATE®

(Fluphenazine Decanoate Injection)

may control schizophrenic symptoms for up to 4 weeks or longer in patients on maintenance therapy.

SQUIBB® "The Priceless Ingredient of every product is the honor and integrity of its maker." ™

For product brief summary see following page.

H425-001R

PROLIXIN DECANOATE®

(Fluphenazine Decanoate Injection)

may control schizophrenic symptoms for up to 4 weeks or longer in patients on maintenance therapy.

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg. fluphenazine decanoate per ml. in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia, liver damage or renal insufficiency, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility that severe adverse reactions may occur which require immediate medical attention. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functions and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. These include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, and hyperreflexia; most often these are reversible, but they may be persistent. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of antiparkinsonian drugs such as benztropine mesylate or intravenous Caffeine and Sodium Benzoate Injection U.S.P., and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may have to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection U.S.P. is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.

HOW SUPPLIED: 1 ml. Unimatic® single dose preassembled syringes and cartridge-needle units, and 5 ml. vials.

SEMINARS IN PSYCHIATRY, Series Editor: Milton Greenblatt

DRUGS IN COMBINATION WITH OTHER THERAPIES

Edited by Milton Greenblatt, M.D.

The book attempts to update all the information on drugs in combination with other therapies in a manner that is both informative and helpful to the clinician in his treatment of cases. Some studies have clearly indicated that certain combinations are superior than single drugs alone. The combination of drugs with such modalities as halfway house and other community therapies are especially relevant to the modern scene. *1975, 224 pp., $14.00/£7.30 ISBN 0-8089-0908-8*

CONSULTATION–LIAISON PSYCHIATRY

Edited by Robert O. Pasnau, M.D.

This book attempts to assess the relationship of liaison psychiatry to general psychiatry and at the same time to clarify what liaison psychiatry is all about, what its premises are, and what it is striving for and how. Presented is a comprehensive effort to put together the recent advances in psychophysiological medicine with psychiatric liaison to special medical and surgical environments, the common problems in general psychiatric consultation, and medical education.

1975, 352 pp., $16.00/£8.30 ISBN 0-8089-0901-0

TOPICS IN PSYCHOENDOCRINOLOGY

Edited by Edward J. Sachar, M.D.

The development of sophisticated techniques and the rapid advances in psychiatric and endocrinologic research has yielded new and systematic data on hormones and human behavior. New and unsuspected possibilities have been uncovered, several of which are discussed in this volume. There is evidence that the pituitary and hypothalamic hormones may of themselves directly affect brain and behavior. The sleep cycle appears to be intimately linked to regulation of hormone secretion. Hormonal influences may also play a role in the early sexual differentiation of the brain. Analysis of hormonal responses in anorexia nervosa and endogenous depressive illness raises the possibility that these conditions are primary hypothalamic disorders with secondary behavioral disturbances. Brain monoamines closely regulate the secretion of the hypothalamic neurohormones, and hormones in turn affect brain monoamine metabolism and function.

1975, 192 pp., $14.95/£7.80 ISBN 0-8089-0888-x

BORDERLINE STATES IN PSYCHIATRY

Edited by John E. Mack, M.D.

The purpose of this volume is to examine the current status of the borderline concept as a diagnostic term or entity in psychiatry. The chapters reflect the use that various practitioners, approaching their clinical cases from differing perspectives and working in different settings, make of the borderline concept. Of particular interest are articles on the effects of drugs in borderline cases, and the problem of supervision of residents therapeutically involved with them.

1975, 160 pp., $13.50/£6.75 ISBN 0-8089-0878-2

PSYCHIATRIC ASPECTS OF NEUROLOGIC DISEASE

Edited by D. Frank Benson, M.D. and Dietrich Blumer, M.D.

The emphasis is toward the clinical characterization of the mental disorders occurring in neurologic disease, and their treatment. Featured are: a new concept in classification of organic mental disease; a new look at acute confusional states, and at treatable dementias; depressive pseudo dementia: behavioral disorders of frontal and temporal lobe disease; the neurology of sex.

1975, 336 pp., $17.50/£8.75 ISBN 0-8089-0860-x

Other new books in psychiatry . . .

CLINICAL HYPNOSIS: PRINCIPLES AND APPLICATIONS

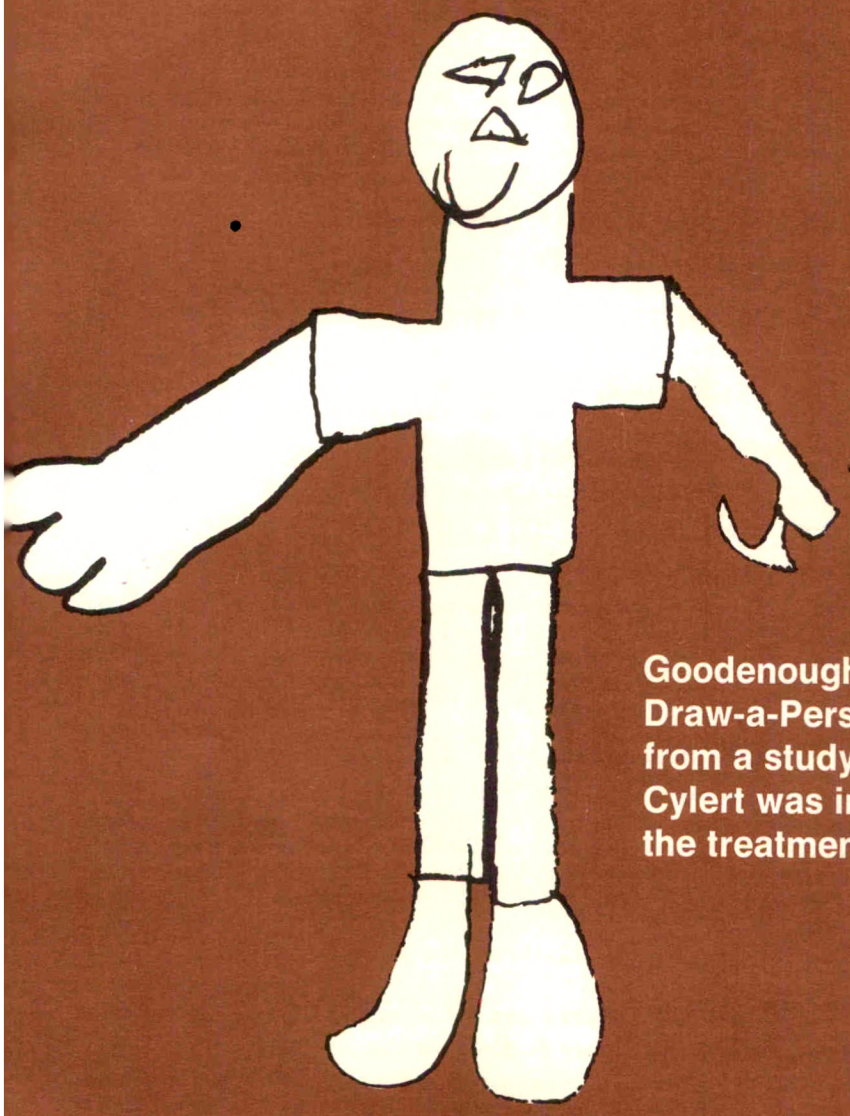
By Harold B. Crasilneck, Ph.D., and James A. Hall, M.D.

Written in a clearly understandable fashion, this monograph provides a comprehensive and authoritative presentation of modern theories and techniques in the control and management of medical, psychological, and dental problems with hypnosis. Among the highlights of this book are a recent review of all professional and scientific literature in clinical hypnosis; chapters on all clinical areas with clear clinical demonstrations and examples of the exact wordings used in the hypnotic treatment of various problems.

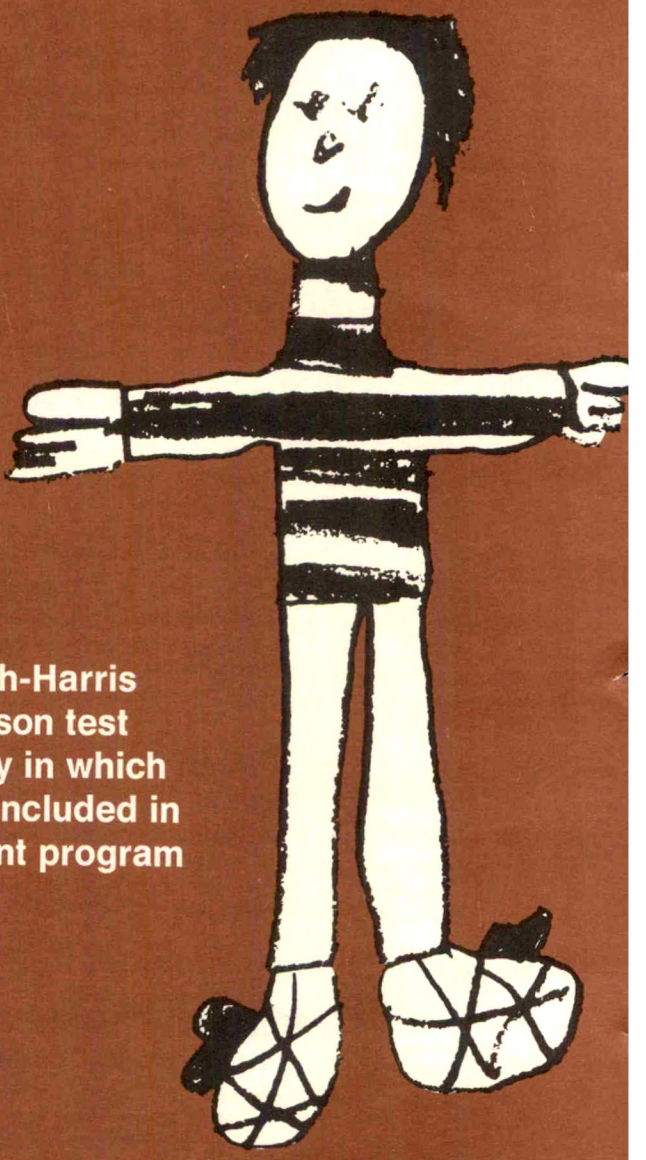
1975, 324 pp., $19.50/£10.15 ISBN 0-8089-0907-x

ELEMENTS OF PSYCHOPATHOLOGY

by Robert B. White, M.D. and Robert M. Gilliland, M.D.



With emphasis on the mechanisms of defense, this presentation offers the student the means to gain the fundamental understanding of psychiatric disorders needed to develop skills for rational therapeutic intervention. All of the basic information needed to fully understand the mechanisms of defense is brought together in a most readable form. The book goes far beyond the early simplistic descriptions of defense mechanisms, putting them in the full context of current theories of anxiety, instinctual drives, ego and superego, and developmental principles including the epigenetic, maturational, and experiential.



1975, 208 pp., $12.00/£6.25 ISBN 0-8089-0913-4

Goodenough-Harris Draw-a-Person test from a study in which Cylert was included in the treatment program

Drawing made prior to treatment

Drawing made at week 8 during treatment

Cylert (pemoline) will not in itself "enhance learning" or resolve difficult behavioral problems. But it can increase attention span in the hyperkinetic child and reduce the impulsivity that often interferes with the learning process.

Cylert®
(pemoline)

offers these benefits in a treatment program for MBD

- **Single daily dose administration**
- **Minimal cardiovascular effects**
- **Mean dosage in long-term studies remained remarkably constant**

UNIVERSITY OF MICHIGAN LIBRARY

EFFICACY

Multi-clinic study[1,2]
21 investigators from 10 states and two provinces in Canada took part in the clinical studies.

Double-blind, placebo control
413 patients were randomly assigned to Cylert or placebo groups. 238 patients met all criteria for evaluation of efficacy.

Psychological test results
Children on Cylert had significantly higher scores statistically than those on placebo on these psychological tests:

- The Wechsler Intelligence Scale for Children (WISC) and its performance IQ Sub-Component
- The Wide Range Achievement Test (WRAT) (reading and arithmetic)
- The Lincoln-Oseretsky Motor Performance Test Factor II

Overall results
Approximately two out of three patients were significantly improved by treatment with Cylert as reflected by global ratings.

2. Page, J. G., et al., J. Learning Disabilities, 7:498, Oct., 1974.

SAFETY

Multi-clinic study (9 weeks); safety data analyzed on 407 patients
There was no significant difference between Cylert and placebo groups in:

- Blood pressure
- Laboratory tests
- Pulse
- Neurological status

Insomnia and anorexia were the most frequently seen side effects and often improved with continuation of treatment or reduction of dosage.

Mean weight loss of 1.1 lbs. was demonstrated in the Cylert group during early weeks of treatment; long-term studies have shown that by 3-6 months, most children return to the normal rate of weight gain for their age group.

Long-term study on Cylert; up to 3 years and continuing

Mean dosage . . . remained remarkably constant.
Blood pressure . . no significant changes attributed to Cylert.
Pulse rate . . . . . no significant changes attributed to Cylert.

Laboratory examination—mild to moderate increase in transaminase (SGOT and SGPT) levels in 1-2% of patients (no clinical symptoms); levels returned to normal on withdrawal of medication.

No clinically significant abnormalities in the other tests.

Please see last page of this advertisement for Prescribing Information.

Importance of single daily dosage to the child, the parents and the teacher

For the child		For the adults
No drug in child's possession while at school	⟷	Control of medication remains with parents
Avoids situation in which child is repeatedly singled out as being "different"	⟷	Obviates need for nurse or teacher to supervise taking of mid-day doses
Helps prevent possible variations in effect caused by missed, forgotten or delayed doses	⟷	Helps assure that the prescribed dosage is being given each day

Cylert (pemoline), alone among CNS stimulants used to treat MBD, is inherently long-acting, permitting once-daily dosage.

Cylert can be taken with meals

You can prescribe Cylert a.c., p.c., or with meals. Although the speed of absorption is slightly slowed by food, the total absorption is not affected.

Dosage and administration

Cylert is given as a single oral dose each morning.

The recommended starting dose is 37.5 mg. per day. This daily dosage should be gradually increased at one-week intervals using increments of 18.75 mg. until the desired clinical response is obtained.

The mean daily effective dose ranges from 56.25 to 75 mg. per day. The maximum recommended daily dose of Cylert is 112.5 mg.

Using the recommended schedule of dose titration, significant benefits may not be seen until the third or fourth week of drug therapy. Side effects may be seen prior to optimum clinical results.

When not to use Cylert

Cylert should not be used for (and will not be effective in) simple cases of overactivity in school-age children.

Neither should it be used in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

The three dosage strengths of Cylert (pemoline)

Cylert, 18.75 mg. (yellow-colored, grooved)

Cylert, 37.5 mg. (orange-colored, grooved)

Cylert, 75 mg. (tan-colored, grooved)

Tablets are actual size.

Cylert
(pemoline) CIV

Prescribing Information

Description: Cylert (pemoline) is a white, tasteless, odorless powder which is relatively insoluble (less than 1 mg/ml) in water, chloroform, ether, acetone, and benzene. In 95% ethyl alcohol, the solubility of pemoline is 2.2 mg/ml.

Actions: Cylert (pemoline) is a central nervous system stimulant. The pharmacologic activity of pemoline is similar to that of other known stimulants but with minimal sympathomimetic effects. Pemoline is structurally dissimilar from the amphetamines and methylphenidate. Although the exact mode of pharmacodynamic action is undetermined in man, pemoline has been reported to increase the rate of synthesis of dopamine in rat brain.

In human subjects, Cylert produces peak blood levels within 2-4 hours. The serum half-life is approximately 12 hours. Multiple dose studies in adults at several dose levels indicate that serum levels plateau in approximately three days. Cylert and its metabolites are primarily excreted by the kidneys with approximately 75% of an oral dose appearing in the urine within a 24-hour period. Approximately 43% of pemoline is excreted unchanged. Metabolites include pemoline dione, conjugated pemoline and mandelic acid.

Cylert (pemoline) has a gradual onset of action in children with minimal brain dysfunction. Using the recommended schedule of dosage titration, significant clinical benefit may not be evident until the third or fourth week of drug administration.

Indications: MINIMAL BRAIN DYSFUNCTION IN CHILDREN—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations: Specific etiology of minimal brain dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis includes the use not only of medical but of psychological, educational, and social resources.

Characteristics commonly reported include: A chronic history of moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindication: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See PRECAUTIONS)

Warnings: Cylert is not recommended for children under six years of age since safety and efficacy in this age group have not yet been established.

Since Cylert (pemoline) and its metabolites are excreted primarily by the kidneys, caution should be observed in administering the drug to children with significantly impaired renal function.

Sufficient data on safety and efficacy of Cylert administration for periods beyond two years duration in children with minimal brain dysfunction are not yet available. Although a definite causal relationship has not been established, some temporary suppression of predicted growth pattern(i.e., weight and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.

Drug Interactions: Interactions between Cylert and other drugs have not been studied in humans. As with most other drugs, concurrent administration with other agents, especially drugs with central nervous system activity, should be carefully monitored.

Usage in Pregnancy: Safety for use in pregnancy has not been established. Standard studies of fertility, teratology and reproduction were conducted in rats and rabbits. Daily oral doses of pemoline of 18.75 and 37.5 mg/kg beginning at conception produced no abnormalities in the fetuses and did not affect viability at birth. Further studies using similar dose levels with drug administration beginning 14 days before conception demonstrated an increased incidence of stillbirths in these animals.

Drug Dependence: Studies of the drug abuse potential of Cylert (pemoline) in primates have not demonstrated a potential for self-administration. However, the pharmacologic similarities between Cylert and other CNS stimulants with known abuse liability suggest that drug dependence of the stimulant type might occur. There have been isolated reports of transient psychotic symptoms in adults following long-term misuse of pemoline taken orally in excessive quantities. Therefore, caution should be observed in emotionally unstable patients considered to have a psychological potential for drug dependence.

Precautions: Delayed hypersensitivity reactions involving the liver have been reported in 1-2% of the patients receiving Cylert usually after several months of therapy. No clinical symptomatology has been observed, but mild to moderate increases in transaminase (SGOT and SGPT) levels have occurred in these cases. These effects appear to be completely reversible when drug treatment is discontinued. Transaminase levels should be determined periodically during therapy with Cylert to detect any such reactions.

Adverse Reactions: The most frequently reported adverse reaction with Cylert is insomnia. Insomnia has been observed prior to optimum therapeutic response and in the majority of cases was transient in nature or responded to dosage reduction. Anorexia with weight loss during the first few weeks of therapy has also been reported. With continuing therapy, a return to a normal weight curve usually occurred within three to six months. Other adverse reactions reported include stomachache, skin rash, irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations. Mild adverse reactions appearing early in treatment often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage reduction or discontinuation should be considered.

Dosage and Administration: Cylert (pemoline) is administered as a single oral dose each morning. The recommended starting dose is 37.5 mg per day. This daily dosage should be gradually increased at one week intervals using increments of 18.75 mg until the desired clinical response is obtained. The mean daily effective dose ranges from 56.25 to 75 mg per day. The maximum recommended daily dose of pemoline is 112.5 mg.

Clinical improvement with Cylert is gradual. Using the recommended schedule of dosage titration, significant benefit may not be evident until the third or fourth week of drug administration. Drug administration should be interrupted occasionally to determine if behavioral symptoms sufficient to require continuing therapy recur.

Overdosage: Cylert overdosage has been reported to produce symptoms of tachycardia, hallucinations, agitation, or restlessness. The treatment of acute massive overdosage with pemoline is essentially the same as that for overdosage with any drug having CNS stimulatory effects. Management is largely symptomatic and may include induction of emesis, gastric lavage or other measures as appropriate.

How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

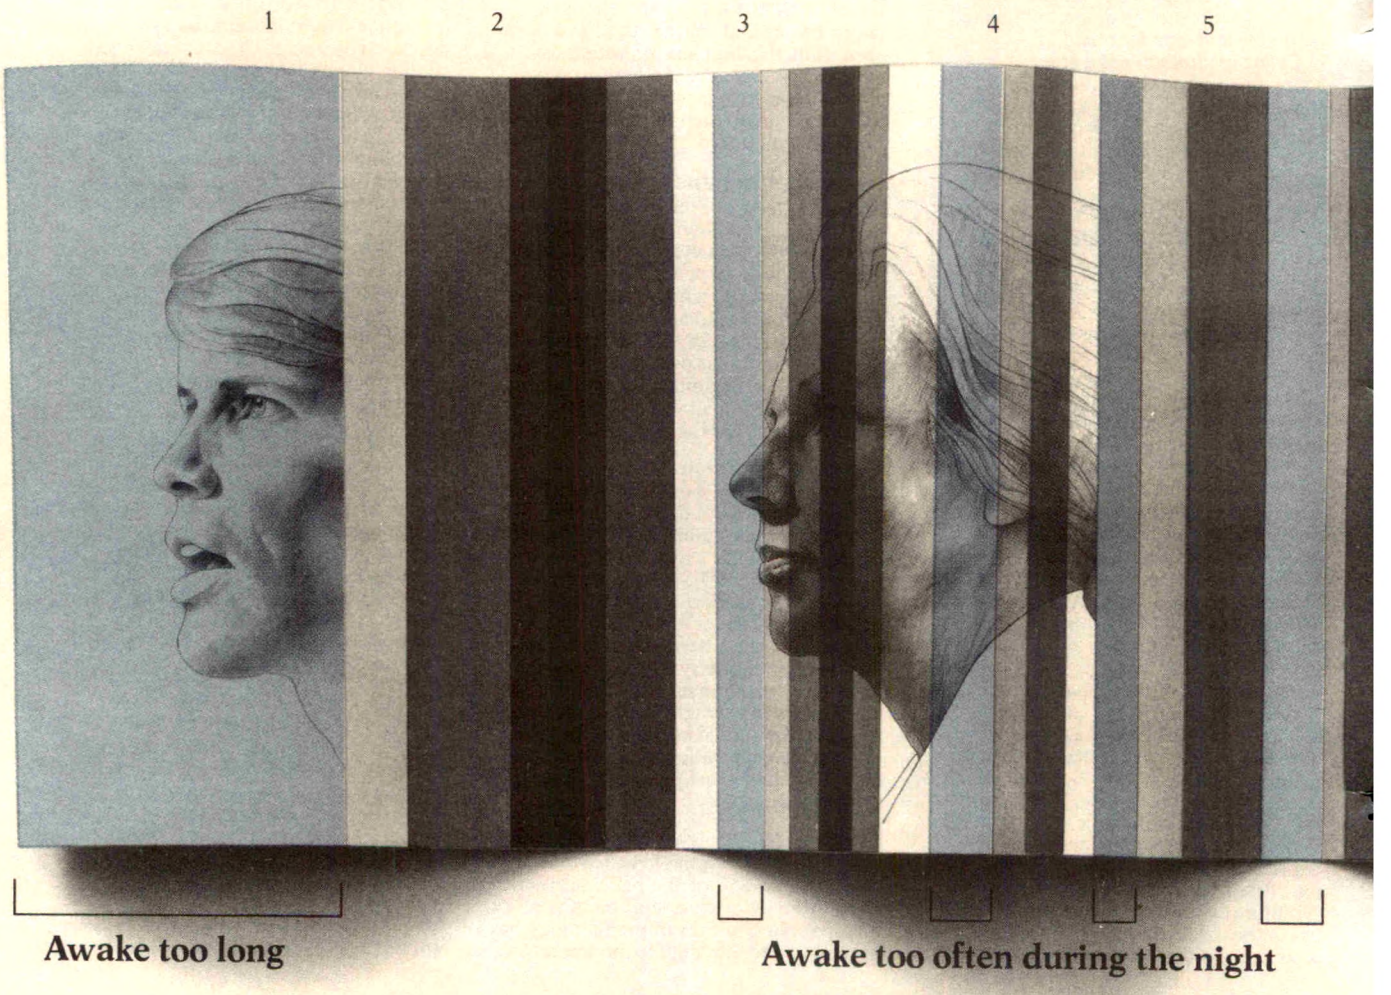
18.75 mg. tablets (yellow-colored) in bottles of 100 (**NDC** 0074-6025-13)

37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6057-13)

75 mg. tablets (tan-colored) in bottles of 100 (**NDC** 0074-6073-13) 6013128R

ABBOTT LABORATORIES
North Chicago, IL60064

Effectiveness across the spectrum of most common forms of insomnia



Awake too long, awake too often, awake too early...

These are the most common forms of insomnia, and may occur singly or in any combination. The night of troubled sleep depicted here comprises all three types. As the night progresses from left to right, each sleep stage is identifiable by its own shade of gray. Blue represents "Awake."

As you can see, this hypothetical "patient" takes well over an hour to fall asleep, awakens several times during the middle of the night and awakens too early in the morning.

Sleep Stages

- Awake
- REM
- Stage 1
- Stage 2
- Stage 3
- Stage 4

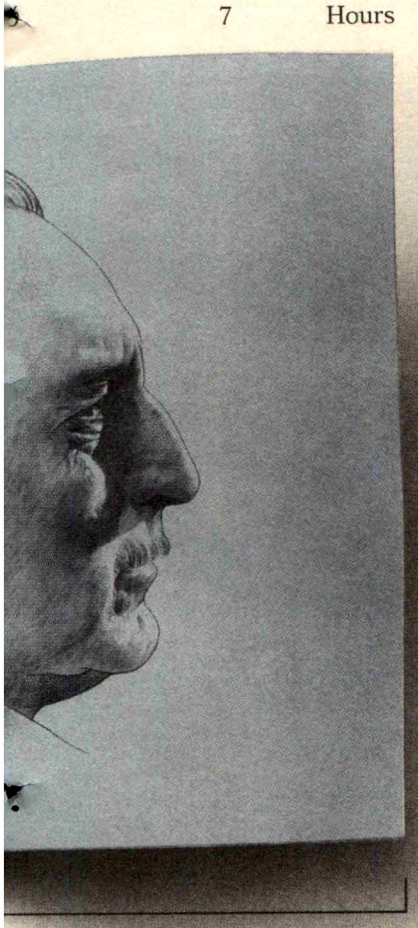
The insomnias most often occurring in young and older adults

For patients with trouble falling asleep (common in young adult insomnia patients), Dalmane (flurazepam HCl) 30 mg provides sleep within 17 minutes, on average. For those with trouble staying asleep or sleeping long enough (common in those over 50), Dalmane offers increased total sleep time with fewer nocturnal awakenings. These clinical results were demonstrated in studies conducted in four geographically separated sleep research laboratories.[1-4]

The relative safety of Dalmane (flurazepam HCl) is well documented

Dalmane (flurazepam HCl) is relatively safe and well tolerated; morning "hang-over" has been infrequent. The usual adult dosage is 30 mg; in elderly or debilitated patients, limit initial dosage to 15 mg to preclude over-sedation, dizziness or ataxia. Caution patients about possible combined effects with alcohol and other CNS depressants.

Broad-spectrum medication for the most common forms of insomnia

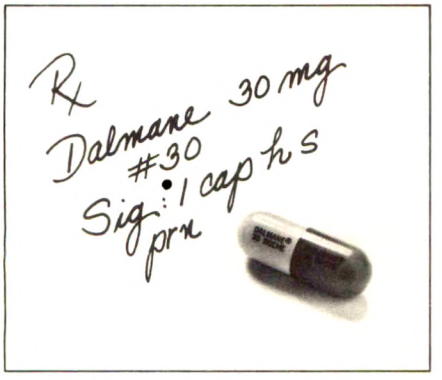


Dalmane®
(flurazepam HCl)

One 30-mg capsule *h.s.*— usual adult dosage
(15 mg may suffice in some patients).
One 15-mg capsule *h.s.*— initial dosage for elderly or debilitated patients.

- □ induces sleep rapidly
- □ reduces nighttime awakenings
- □ lengthens total sleep time

ROCHE



Awake too early

Please see following page for a summary of complete product information.

Broad-spectrum medication for the most common forms of insomnia

Dalmane®
(flurazepam HCl) Ⓒ IV

Objectively proved in the sleep research laboratory, Dalmane

- induces sleep within 17 minutes, on average
- reduces nighttime awakenings
- provides 7 to 8 hours sleep, on average, without repeating dosage

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:

Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; and in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.

Contraindications: Known hypersensitivity to flurazepam HCl.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Use in women who are or may become pregnant only when potential benefits have been weighed against possible hazards. Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.

Precautions: In elderly and debilitated, initial dosage should be limited to 15 mg to preclude oversedation, dizziness and/or ataxia. If combined with other drugs having hypnotic or CNS-depressant effects, consider potential additive effects. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.

Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported were headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase. Paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, have also been reported in rare instances.

Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until response is determined.

Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

when you want *maintenance* therapy for *cooperative* patients, in the hospital or at home

benefits
- **generally improve cooperation and communication**
- **decrease need for custodial care, hasten discharge**

Trilafon®
brand of perphenazine, NF
Tablets
REPETABS® Tablets
Concentrate
Injection

CONTRAINDICATIONS TRILAFON is contraindicated in drug-associated central nervous system depression (barbiturates, alcohol, narcotics, analgesics, antihistamines). Perphenazine is contraindicated in the presence of existing blood dyscrasias, bone marrow depression and pre-existing liver damage, and in patients who are hypersensitive to perphenazine.

TRILAFON **Injection** should not be given to patients in coma or severely depressed states.

WARNINGS **Usage in pregnancy:** Perphenazine should only be given to pregnant patients when, in the judgment of the physician, the potential benefits outweigh the possible risks.

Perphenazine can lower the convulsive threshold in susceptible individuals; it should be used with caution in patients with convulsive disorders. If the patient is being treated with an anticonvulsant agent, increased dosage of that agent may be required when perphenazine is used concomitantly.

Perphenazine should be used with caution in patients with psychic depression.

Perphenazine is not recommended for children under 12 years of age.

Perphenazine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as driving a car or operating machinery.

PRECAUTIONS As with any potent medication, patients receiving perphenazine should be under medical supervision, particularly if they are receiving high doses. Patients who have had any severe reaction to phenothiazines or to imipramine should be treated cautiously, under close medical supervision.

Although the following adverse reactions have not been reported in patients treated with perphenazine, the possibility that they might occur with TRILAFON should be considered: blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, eosinophilia); liver damage (biliary stasis); narrowing of the visual fields; pigmentation of the retina, cornea, or lens; cerebral edema; polyphagia; photophobia; hyperpyrexia.

If hypotension develops, levarterenol (norepinephrine) can be used, but not epinephrine, because epinephrine's action is blocked and partly reversed by perphenazine. Severe, acute hypotension has occurred with the use of phenothiazines and is of particular concern in patients with mitral insufficiency or pheochromocytoma.

A significant rise in body temperature may indicate an idiosyncratic reaction to perphenazine; treatment with perphenazine should be stopped if this occurs.

The antiemetic effect of perphenazine can obscure signs of toxicity due to overdosage of other drugs, or mask the symptoms of disease (eg, brain tumor or intestinal obstruction).

Contact dermatitis has been reported with a perphenazine solution; therefore, contact of hands or clothing by those handling perphenazine solutions should be avoided.

POTENTIATION Since phenothiazines can potentiate the central-nervous-system-depressant actions of opiates, antihistamines, barbiturates, and alcohol, less than the usual dosage of these agents is required when they are administered concomitantly with TRILAFON. Patients should be cautioned that their response to alcohol may be increased while they are being treated with TRILAFON.

Phenothiazines also potentiate the effects of atropine, heat, and phosphorus insecticides, and should be used with caution in persons exposed to these agents.

ADVERSE REACTIONS *Extrapyramidal reactions:* dystonia including protrusion, discoloration, aching and rounding of the tongue; tonic spasm of the masticatory muscles, tight feeling in the throat, slurred speech, dysphagia, oculogyric crisis, trismus, torticollis, retrocollis, muscle weakness, and aching and numbness of the limbs; akathisia; motor restlessness; dyskinesia, parkinsonism; hyperreflexia; and ataxia. The incidence and severity of these reactions usually increase with increased dosage, but have occurred in some patients receiving low dosage. Reduction in dosage or treatment with an antispasmodic agent will usually control extrapyramidal reactions. In some instances, however, these reactions may persist after discontinuation of treatment with perphenazine.

Persistent tardive dyskinesia: As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities. There is no known effective treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine, vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Allergic reactions: erythema, pruritus, urticaria, eczema, anaphylactoid reactions, and local and generalized edema. In extremely rare instances, individual idiosyncrasy or hypersensitivity to phenothiazines has resulted in cerebral edema, circulatory collapse, and death. Photosensitization, asthma, and exfoliative dermatitis have also occurred in patients treated with phenothiazines.

Autonomic reactions: blurred vision, dry mouth or salivation, nasal congestion, nausea, vomiting, hypertension, tachycardia, hypotension, anorexia, urinary frequency or incontinence, and constipation. Significant autonomic effects have been infrequent in patients receiving less than 24 mg. perphenazine daily.

Other reactions: endocrine disturbances (lactation, gynecomastia, galactorrhea, disturbances in the menstrual cycle), headaches, mild insomnia, altered cerebrospinal fluid proteins, ECG abnormalities, reactivation of psychosis, paradoxical excitement, paranoid-like reactions, catatonia, and systemic lupus erythematosus-like syndrome. Hypnotic effects appear to be minimal, particularly in patients who are permitted to remain active. The following adverse reactions, though rare, have also been reported to be associated with perphenazine treatment: agranulocytosis; jaundice; hyperpigmentation of the skin; grand mal convulsions; failure of ejaculation; hyperglycemia.

Side effects with intramuscular TRILAFON **Injection** have been infrequent and transient. Dizziness or significant hypotension after treatment with TRILAFON **Injection** is a rare occurrence.

CHARLES C THOMAS · PUBLISHER

ARMED ROBBERY: Offenders and Their Victims *by* **John M. Macdonald,** *Univ. of Colorado, Denver. Chapters by* **Lieutenant C. Donald Brannan.** The author of this book has conducted psychiatric evaluations for the courts of over 100 armed robbers, including twenty-five who killed during the robbery. Reasons for committing the crime as well as various methods of committing the crime are covered in detail. The actual words used by the robber to describe the crime, the use of violence and his experiences "on the run" are quoted at length. The victim also tells his own story and contributes to the understanding of the crime and its impact on victims. With an awareness of the admiration and fear of the armed robber which has existed in past centuries, the author gives lengthy consideration to the Robin Hood tradition. *'75, 456 pp., 8 tables, $18.50*

THE CLINICAL APPLICATION OF PROJECTIVE DRAWINGS (4th Ptg.) *edited by* **Emanuel F. Hammer,** *New York Univ., New York. (14 Contributors)* A classic in this field, this book provides fundamentals of projective drawings, and goes on to considerations of differential diagnosis, appraisal of psychodynamics, conflict and defense, psychological resources as treatment potentials, and projective drawing usage in therapy. In addition to Buck's H-T-P Technique and Machover's Draw-A-Person Test, the book also includes the Draw-A-Family Procedure, Harrower's Unpleasant Concept Test, Kinget's Drawing Completion Test, and the Eight Card Redrawing Test which is useful in disclosing the deepest layers of the subject's psychosexual identification. *'75, 688 pp., 360 il., $18.50*

A PRACTICAL HANDBOOK OF PSYCHIATRY *edited by* **Joseph R. Novello,** *Univ. of Michigan Medical School, Ann Arbor. (17 Contributors)* For the first time, information on continuing education for psychiatrists is brought together along with a compendium of training programs, referral hospitals, and professional organizations. Information is summarized in tables and outlined in the tradition of the popular handbooks that are available in medicine and surgery and other specialties. Part I, "A Guide to Clinical Practice" provides a discussion of practical problems, tools and techniques of the psychiatrist and includes the complete, official *Diagnostic and Statistical Manual.* Part II, "A Guide to Continuing Education" includes basic reading lists and journals in psychiatry, training opportunities and information on Board Examinations. Part III provides over 700 useful mailing addresses. *'74, 648 pp., 10 il., 47 tables, $16.75*

BEHAVIOR MODIFICATION WITH CHILDREN: A Clinical Training Manual *by* **Alexander J. Tymchuk,** *Univ. of California, Los Angeles.* This informative and easily read book is intended for professionals and parents who are interested in applying operant learning techniques with behaviorally disturbed, mentally retarded, or emotionally disturbed children. Certain chapters describe the parent and student training programs along with instructions on how to conduct a parent training group. Case studies include children who were aggressive, learning disabled or hyperactive. *'74, 144 pp., 20 il., 30 tables, cloth-$9.75, paper-$6.95*

ADOLESCENT MEDICINE: Principles and Practice *by* **I. Newton Kugelmass,** *Consultant to the Departments of Health and Hospitals, New York.* The movement of adolescent life in health and disease has its own hidden harmony of basic systems – biological, psychological and social. Problems with adolescents must be evaluated scientifically by applying the newer knowledge in experimental medicine and then clinically allowing the professional's own individuality to interact with that of the adolescent to lay bare such weaknesses as latent or manifest disorders in deficient development, delayed maturation and deviant function, body-mind derangement, objective-subjective disorder, inner-outer sense discord and self-nonself damage in youth who are poorly programmed for adult life. *'75, 584 pp., 3 il., 11 tables, $23.75*

UNUSUAL SEXUAL BEHAVIOR: The Standard Deviations *by* **David Lester,** *Richard Stockton State College, Pomona, New Jersey.* The primary concern in this book is with research literature and not clinical studies. However, occasional reference is made to the conclusions of clinical studies and to psychoanalytic hypotheses about sexual deviations. The author proposes a classification of sexual deviations which includes three kinds of deviant behavior: variation of mode which refers to deviations in the manner of obtaining sexual satisfaction, variation of object which refers to deviations in the choice of stimulus which provides sexual satisfaction, and variation in strength of the sexual response which refers to deviations in the frequency and intensity of sexual behavior. *'75, 256 pp., $16.75*

LESBIANISM: A Study of Female Homosexuality *by* **David H. Rosen,** *Univ. of California, San Francisco. Foreword by* **Doctor Evelyn Hooker.** This text takes lesbianism out of the subjective mythical and psychoanalytical theory stages and brings it into an objective phenomenological and existential realm. Judd Marmor states: "I found it of great interest as part of the growing list of recent efforts to study homosexuals as human beings without prejudiced preconceptions concerning 'mental illness' or 'mental abnormality.' . . . Doctor Rosen's study of twenty-six lesbians is a valuable addition to the literature in this area. Although his volume is a slender one it contains a great deal of useful and important information." *'74, 140 pp., 28 il., 3 tables, cloth-$7.95, paper-$4.95*

CHILDHOOD DEPRIVATION *compiled and edited by* **Albert R. Roberts,** *Coppin State College, Baltimore, Maryland. (13 Contributors)* The authors of this book have placed the focus on etiology, treatment methods and prevention with case histories often illustrating specific behavior disorders. Childhood experiences discussed which are likely to be traumatic for the child include lack of affection, foster home placement, institutionalization, divorce of parents, death of a loved one, and poverty. Other chapters focus on physical abuses and prolonged isolation of children. Detailed illustrations are provided of behavioral problems such as juvenile delinquency, acting out, temper tantrums, speech impediments and depression which can result from deprivation during childhood. *'74, 232 pp., 1 table, cloth-$9.75, paper-$6.95*

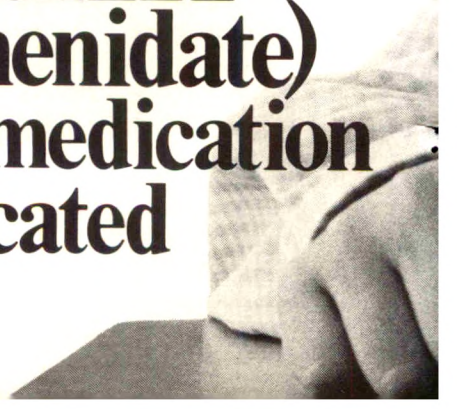
Tested by time and experience in

1962

"...a considerable decrease of hyperactivity...."[1]
Knobel, 1962

Over a decade of controlled studies and clinical experience has shown the effectiveness of Ritalin in reducing the hyperactivity,[1-3] distractibility,[1,4,5] and disorganized behavior[1-8] in the MBD child.

By lessening the effects of motor and attentional disorders, Ritalin can help the MBD child to better focus his attention on meaningful stimuli and thus can often improve cognition and promote learning.[6,9]



And side effects – insomnia and appetite loss – with Ritalin have occurred less frequently than with dextroamphetamine.[10,11]

Indeed, Ritalin is currently a drug of choice in many MBD situations,[10,12] and can prove to be an important element in many complete remedial programs for MBD.

Therapy with Ritalin should be undertaken only after a medical diagnosis of MBD has been made. Drug treatment is not indicated for all children with MBD.

Dosage should be periodically interrupted. Often, these interruptions reveal some "stabilization" in the child's behavior even without medication, permitting a reduction in dosage and eventual discontinuance of drug therapy.

TABLETS

INDICATION

Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)

Special Diagnostic Considerations

Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis. Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation, since Ritalin may aggravate these symptoms. Also contraindicated in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.

Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain and/or height) has been reported with long-term use of stimulants in children. Therefore, children requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin or for the prevention of normal fatigue states.

Ritalin may lower the convulsive threshold in patients with or without prior seizures; with or without prior EEG abnormalities, even in absence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. If seizures occur, Ritalin should be discontinued.

Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors. Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include: hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.

In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION

Children with Minimal Brain Dysfunction (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.

Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-pak® blister units of 100.

Tablets, 5 mg (pale yellow); bottles of 100, 500, and 1000.

Consult complete product literature before prescribing.

CIBA

No default insurance

Tofranil-**PM**®
imipramine **pamoate**

Geigy

In depression

Daily Dosage Chart

1 h.s.

A major reason for drug defaulting is multiple daily dosage schedules.

Ayd* reports that 70 percent of patients default on a q.i.d. regimen; 60 percent on t.i.d.; 30 percent on b.i.d., and only 7 percent on a single daily dose.

A single daily capsule that provides a full day's medication would logically assure better therapeutic results.

Because one capsule lasts from bedtime to bedtime, Tofranil-**PM**® may markedly reduce the probability of missed doses.

After therapy is initiated with the 75-mg. capsule, the 150-mg. capsule is the dose level at which optimum response is usually obtained.

Please review the prescribing information summarized on the back of this page.

*Ayd, F.J., Jr. (Ed.): Int. Drug Ther. Newslett. 7(9/10):35-50 (Nov./Dec.) 1972.

Tofranil-PM®
imipramine

One capsule lasts from bedtime to bedtime

...ose For Maintenance Therapy

...arting ...ose	Usual Optimum Response Dose	A Full Range to Choose From*			
					
75 mg.	150 mg.	150 mg.	125 mg.	100 mg.	75 mg.

*Each capsule contains imipramine pamoate equivalent to 150, 125, 100 or 75 mg. of imipramine hydrochloride.

Tofranil-PM®
brand of imipramine pamoate

Indications: For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications: The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM, brand of imipramine pamoate, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings: *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of this drug, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

—patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
—patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
—hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
—patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
—patients receiving guanethidine or similar agents since imipramine may block the pharmacologic effects of these drugs.

Since imipramine may impair the mental and or physical abilities required for the performance of potentially hazardous tasks such as operating an automobile or machinery, the patient should be cautioned accordingly.

Usage in Children: Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Precautions: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil-PM, brand of imipramine pamoate, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil-PM, brand of imipramine pamoate, may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g., paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Avoid the use of preparations, such as decongestants and local anesthetics, which contain any sympathomimetic amine (e.g., adrenalin, noradrenalin), since it has been reported that tricyclic antidepressants can potentiate the effects of catecholamines.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Adverse Reactions: Note: Although the listing which follows includes a few adverse reactions which have not been reported with this specific drug, the pharmacological similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when imipramine is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue); drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea; peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: In adult outpatients, therapy should be initiated on a once-a-day basis with 75 mg. day. This may be increased to 150 mg. day which is the dose level which usually obtains optimum response.If necessary, dosage may be increased to 200 mg. day. Dosage should be modified as necessary by clinical response and any evidence of intolerance. Daily dosage may be given at bedtime, or in some patients in divided daily doses.

Hospitalized patients should be started on a once-a-day basis with 100-150 mg. day and may be increased to 200 mg. day. Dosage should be increased to 250-300 mg. day if there is no response after two weeks. Following remission, maintenance medication may be required for a longer period of time at the lowest dose that will maintain remission. The usual adult maintenance dosage is 75-150 mg. day on a once-a-day basis, preferably at bedtime.

In adolescent and geriatric patients, capsules of Tofranil-PM, brand of imipramine pamoate, may be used when total daily dosage is established at 75 mg. or higher. It is generally unnecessary to exceed 100 mg. day in these patients. This dosage may be given once a day at bedtime or, if needed, in divided daily doses.

How Supplied: Tofranil-PM, brand of imipramine pamoate: Capsules of 75, 100, 125 and 150 mg. (Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg. of imipramine hydrochloride.)

Basic tools of primitive psychiatry

Konde: Incarnation of *Ndoki*, an evil spirit which causes disease. Wish-projection "causes" illness when a nail is driven into the statue. Also used to "drive out" an illness. Bakongo, Zaire.

Mask: Represents the spirit of the underworld. Used by the Ekpo male society, which honors dead ancestors and enforces the law. Anang Ibibio, Nigeria.

Objects from the collection of the Segy Gallery, New York City.

Basic tool of Western psychiatry

Thorazine®

brand of chlorpromazine

Tablets: 25 mg. of the HCl

- 'Thorazine' controls psychotic symptoms
- Especially useful in agitated, violent or anxious schizophrenic patients
- Unsurpassed clinical experience
- 18 dosage forms and strengths

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings: Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudo-parkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg.; Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

Effective control of psychotic agitation

Suspicious and hostile?

Consider the advantages of starting her on HALDOL® (haloperidol)

Acts promptly to control hostility and suspiciousness

Several clinicians have cited the special value of HALDOL haloperidol in controlling hostility, suspiciousness, ideas of persecution and other delusions associated with psychoses.[1-6] Symptom control is achieved rapidly, with many patients showing distinct improvement in a few days to a week[1,6]—frequently within a few hours when the intramuscular form is used for initial control of acutely agitated psychotic states.[7,8]

Usually leaves patients relatively alert and responsive

Although some instances of drowsiness have been observed, marked sedation with HALDOL haloperidol is rare. In fact, this drug has been reported to increase activity in some underactive patients, while in hyperactive patients it usually reduces activity to a normal level without somnolence. HALDOL haloperidol has been found to "normalize" behavior and produce a sensitivity to the environment that allows more effective use of the social milieu and the therapeutic community.[4]

Reduces likelihood of certain adverse reactions

HALDOL haloperidol, a butyrophenone, avoids or minimizes many of the problems associated with the phenothiazines. The most commonly noted side effects of HALDOL haloperidol—extrapyramidal reactions—are usually dose-related and readily controlled with antiparkinson drugs.

Transient hypotension occurs rarely; severe orthostatic hypotension has not been reported. HALDOL haloperidol is also unlikely to cause hepatic damage, serious hematologic reactions, photosensitivity reactions and skin rashes. Ocular damage and pigmentation changes have not been reported.

HALDOL®
(haloperidol)
tablets/concentrate/injection

highly specific control of disordered and disruptive behavior

For information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions, please turn page.

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

©McNeil Laboratories, Inc., 1975

HALDOL®
(haloperidol)
tablets/concentrate/injection

highly specific control of disordered and disruptive behavior

A Dosage Form for Every Need:

5 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg., 5 mg. and 10 mg.

An undetectable, tasteless liquid concentrate for the patient unable or unwilling to swallow tablets: 2 mg. per cc.

A rapid-acting injection for psychiatric emergencies: 5 mg. per cc., with 0.5 mg. methylparaben and 0.05 mg. propylparaben per cc., and lactic acid for pH adjustment to 3.4±0.2.

Indications: HALDOL haloperidol is indicated for use in the management of manifestations of psychotic disorders.

It is also indicated for the control of tics and vocal utterances of Gilles de la Tourette's syndrome.

Contraindications: HALDOL haloperidol is contraindicated in patients who are severely depressed, comatose, have CNS depression due to alcohol or other centrally-acting depressants, have Parkinson's disease or are hypersensitive to this drug.

Warnings: ***Usage in Pregnancy:*** Safe use of HALDOL haloperidol in pregnancy and lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the possible benefits of the drug be weighed against the potential hazards. A case of phocomelia in an infant whose mother received haloperidol along with a number of other medications during the first trimester of pregnancy has been reported (a causal relationship was not established in this case). Animals receiving 2 to 20 times the maximum human dose of haloperidol orally and/or parenterally showed increased incidence of resorption, reduced fertility, delayed delivery, dose-related pup mortality (presumably due to lack of maternal care reflecting CNS depression).

Usage in Children: Safety and effectiveness in children have not been established; therefore, this drug is not recommended for use in the pediatric age group.

General: Cases of bronchopneumonia, some fatal, have followed the use of major tranquilizers, including haloperidol. It has been postulated that lethargy and decreased sensation of thirst may lead to dehydration, hemoconcentration and reduced pulmonary ventilation. If these signs and symptoms appear, especially in the elderly, the physician should institute remedial therapy promptly. Although not reported with HALDOL haloperidol, decreased serum cholesterol and/or cutaneous and ocular changes have been reported in patients receiving chemically-related drugs. HALDOL haloperidol may impair the mental and/or physical abilities required for the performance of hazardous tasks such as operating machinery or driving a motor vehicle. The ambulatory patient should be warned accordingly. The use of alcohol should be avoided due to possible additive effects and hypotension.

Precautions: HALDOL haloperidol should be administered cautiously to patients: (1)—with severe cardiovascular disorders, because of the possibility of transient hypotension and/or precipitation of anginal pain. Should hypotension occur and a vasopressor be required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur. (2)—receiving anticonvulsant medication, because HALDOL haloperidol may lower the convulsive threshold. Adequate anticonvulsant therapy should be maintained concomitantly. (3)—with known allergies, or with a history of allergic reactions to drugs. (4)—receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione).

If concomitant antiparkinson medication is required, it may have to be continued after HALDOL haloperidol is discontinued because of the difference in excretion rates. If both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson agents, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used to control mania in cyclic disorders there may be a rapid mood swing to depression.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which usually were mild to moderately severe and reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Administration of antiparkinson drugs may be required for control of such reactions. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Persistent Tardive Dyskinesia*—Tardive dyskinesia may appear during long-term therapy or after therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. There is no known effective treatment. All antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports have appeared of mild and usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis. Agranulocytosis has rarely been reported and then only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice have been reported, although a causal relationship has not been established. ***Dermatologic Reactions:*** Maculopapular and acneiform skin reactions and isolated cases of photosensitivity and loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

Complete dosage information available in insert which accompanies each package (or on request).

The use of the injectable form is intended for the acutely agitated psychotic patient with moderately severe to very severe symptoms.

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed. 9/74

Psychological Medicine

Editor
Michael Shepherd, Institute of Psychiatry, University of London

Psychological Medicine publishes original research in clinical psychiatry and the related basic sciences — not only the several fields of biological inquiry traditionally associated with medicine, but also the various psychological and social sciences whose relevance to medicine has become increasingly apparent. Book reviews are included regularly, and commissioned review articles and editorials are published from time to time.

Published quarterly.

Subscription to Volume 6 (1976): $28.00 for individuals, $48.50 for institutions.

Teaching Social Change

A Group Approach

Norman E. Zinberg, Harold N. Boris, and Marylynn Boris

Speaking directly to guidance counselors and psychiatrists, *Teaching Social Change* describes an innovative method of social education. From an experimental project that was mounted over a four-year period in the Boston area, the authors devised a group approach which emphasizes the process by which people attempt to discover and express their attitudes toward socially sensitive topics such as drugs, sex, and race. $12.95

4th edition

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

LIBRIUM®
(chlordiazepoxide HCl)
5 mg, 10 mg, 25 mg capsules

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

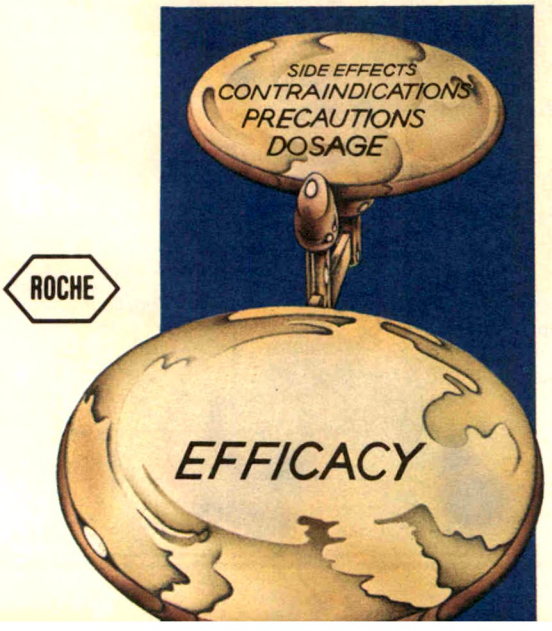
Nutley, New Jersey 07110

SAFETY. IT'S A QUESTION OF BALANCE.

In choosing a tranquilizer for the patient whose excessive anxiety is disrupting psychotherapy there are a number of things to consider. One is effectiveness. A second is safety.



The first is more easily established. The second may be ascertained by comparison. In other words, with safety there is the question of balancing a drug's potential benefits against any potential risks.

When the antianxiety agent you are considering is Librium, you should know that it has a wide margin of safety.

The most common side effects of Librium are dose-related and thus largely avoidable. There appears to be a low incidence of drug dependence and tolerance. Librium rarely has any adverse effects on the cardiovascular or respiratory systems, and there are relatively few cases of known toxicity attributable to Librium.

You already know that Librium is effective. But you should also know that Librium, used in proper dosage, rarely interferes with mental acuity and thus is unlikely to interfere with the psychotherapeutic process. In addition, Librium is used concomitantly with many primary medications.

Librium. All in all, a very good balance.

A Timely New Book from The Joint Information Service

This latest Joint Information Service field study provides a concise, comprehensive overview of the complex matter of the very young American child and his mental health, and then describes in intimate detail seven unique programs for pre-school children with problems—from North Hollywood's Dubnoff Center, emphasizing education as its primary therapeutic modality, to Baltimore's Martin Luther King, Jr. Parent-Child Center, serving two housing projects, served by Johns Hopkins, and largely governed by its own people. All different in treatment approach and philosophy, the programs described are uniform in their dedication to innovation in improving service to the emotionally disturbed very young child, and, equally, to the emotional well being of all young children.

This thoughtful and perceptive description of what has been created by some of the best informed, most experienced and thoughtful specialists in mental health services for very young children should be welcome to all involved in the mental health of children and a casebook for those dealing with child and family mental health.

An articulate exposition of the immense problems and encouraging accomplishments in a particularly difficult area of endeavor . . . . Beyond their concern with the manifestly ill child, the authors intriguingly explore what may be needed to enhance the mental good health of all young children . . . . A significant contribution.

James N. Sussex, M.D.
President, American Association of Psychiatric Services for Children

Exhibited certain favorable trends in side effects profile

IN 31 STUDIES INVOLVING 469 ACUTE AND CHRONIC SCHIZOPHRENIC PATIENTS, CERTAIN FAVORABLE TRENDS WERE EXHIBITED IN THE LOXITANE SIDE EFFECTS PROFILE; THESE REQUIRE FURTHER TESTS AND BROADER CLINICAL EXPERIENCE FOR CONFIRMATION.

While cardiac arrest, blood dyscrasias and renal toxicity have been reported with other antipsychotic agents, they have not been seen with LOXITANE. Hepatotoxicity manifested by jaundice or biliary stasis has not been observed. Transient liver enzyme changes, however, have been reported, but it has not been determined whether they are related to LOXITANE administration.

Although a few cases of changes in ECG have been reported, a causal relationship between this reaction and LOXITANE has not been established. Clinical experience with LOXITANE has not demonstrated ocular toxicity; however, the possibility of its occurrence cannot be ruled out at this time. Of the various endocrine abnormalities, only galactorrhea has been reported with LOXITANE and only in rare instances. Manifestations of adverse effects on the central nervous system other than extrapyramidal symptoms have been encountered infrequently, and drowsiness, when it occurs, is usually mild and subsides with continued therapy. Skin rashes of uncertain etiology have been observed in a few patients during the hot summer months; therefore the possibility of phototoxicity and/or photosensitivity cannot be excluded.

In general, LOXITANE presents a profile of extrapyramidal side effects similar to that of other agents used in the treatment of schizophrenia.

Cardiovascular effects such as hypotension, hypertension, lightheadedness and syncope have been reported. Anticholinergic effects seen with LOXITANE include dry mouth, nasal congestion, constipation and blurred vision.

arnings and precautions and for more detailed information concerning side effects.

FOR ORAL USE

PRODUCT INFORMATION

DESCRIPTION

LOXITANE *loxapine*, a dibenzoxazepine compound, represents a new subclass of tricyclic antipsychotic agent, chemically distinct from the thioxanthenes, butyrophenones, and phenothiazines. Chemically, it is 2 - chloro - 11 - (4 - methyl - 1 - piperazinyl) dibenz [b,f] [1,4] oxazepine. It is present in capsules as the succinate salt. Each 1.36 mg of loxapine succinate is equivalent to 1 mg of loxapine.

ACTIONS

Pharmacologically, loxapine is a tranquilizer for which the exact mode of action has not been established. However, changes in the level of excitability of subcortical inhibitory areas have been observed in several animal species in association with such manifestations of tranquilization as calming effects and suppression of aggressive behavior.

In normal human volunteers, signs of sedation were seen within 20 to 30 minutes after administration, were most pronounced within 1½ to 3 hours, and lasted through 12 hours. Similar timing of primary pharmacologic effects was seen in animals.

Absorption of loxapine following oral or parenteral administration is virtually complete. The drug is removed rapidly from the plasma and distributed in tissues. Animal studies suggest an initial preferential distribution in lungs, brain, spleen, heart, and kidney. Loxapine is metabolized extensively and is excreted mainly in the first 24 hours. Metabolites are excreted in the urine in the form of conjugates and in the feces unconjugated.

INDICATIONS

LOXITANE *loxapine succinate* is indicated for the manifestations of schizophrenia.

CONTRAINDICATIONS

LOXITANE is contraindicated in comatose or severe drug-induced depressed states (alcohol, barbiturates, narcotics, etc.)

LOXITANE is contraindicated in individuals with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Safe use of LOXITANE *loxapine succinate* during pregnancy or lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the benefits of treatment be weighed against the possible risks to mother and child. No embryotoxicity or teratology was observed in studies in rats, rabbits or dogs, although with the exception of one rabbit study, the highest dosage was only two times the maximum recommended human dose and in some studies they were below this dose. Perinatal studies have shown renal papillary abnormalities in offspring of rats treated from midpregnancy with doses of 0.6 and 1.8 mg/kg, doses which approximate the usual human dose but which are considerably below the maximum recommended human dose.

Usage in Children: Studies have not been performed in children; therefore this drug is not recommended for use in children below the age of 16.

LOXITANE, like other tranquilizers, may impair mental and/or physical abilities, especially during the first few days of therapy. Therefore, ambulatory patients should be warned about activities requiring alertness (eg, operating vehicles or machinery), and about concomitant use of alcohol and other CNS depressants.

PRECAUTIONS

LOXITANE loxapine succinate should be used with extreme caution in patients with a history of convulsive disorders since it lowers the convulsive threshold. Seizures have been reported in epileptic patients receiving LOXITANE at antipsychotic dose levels, and may occur even with maintenance of routine anticonvulsant drug therapy.

Loxapine has an antiemetic effect in animals. Since this effect may also occur in man, loxapine may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

LOXITANE should be used with caution in patients with cardiovascular disease. Increased pulse rates have been reported in the majority of patients receiving antipsychotic doses; transient hypotension has been reported. In the presence of severe hypotension requiring vasopressor therapy, the preferred drugs may be norepinephrine or angiotensin. Usual doses of epinephrine may be ineffective because of inhibition of its vasopressor effect by loxapine.

The possibility of ocular toxicity from loxapine cannot be excluded at this time. Therefore, careful observation should be made for pigmentary retinopathy and lenticular pigmentation since these have been observed in some patients receiving certain other antipsychotic drugs for prolonged periods.

Because of possible anticholinergic action, the drug should be used cautiously in patients with glaucoma or a tendency to urinary retention, particularly with concomitant administration of anticholinergic-type antiparkinson medication.

ADVERSE REACTIONS

CNS Effects: Manifestations of adverse effects on the central nervous system, other than extrapyramidal effects, have been seen infrequently. Drowsiness, usually mild, may occur at the beginning of therapy or when dosage is increased.

It usually subsides with continued LOXITANE therapy. The incidence of sedation has been less than that of certain aliphatic phenothiazines and slightly more than the piperazine phenothiazines. Dizziness, faintness, staggering gait, muscle twitching, weakness, and confusional states have been reported.

Extrapyramidal Reactions—Neuromuscular (extrapyramidal) reactions during the administration of LOXITANE *loxapine succinate* have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved Parkinson-like symptoms such as tremor, rigidity, excessive salivation, and masked facies. Akathisia (motor restlessness) also has been reported relatively frequently. These symptoms are usually not severe and can be controlled by reduction of LOXITANE dosage or by administration of antiparkinson drugs in usual dosage. Dystonic and dyskinetic reactions have occurred less frequently, but may be more severe. Dystonias include spasms of muscles of the neck and face, tongue protrusion, and oculogyric movement. Dyskinetic reaction has been described in the form of choreo-athetoid movements. These reactions sometimes require reduction or temporary withdrawal of LOXITANE dosage in addition to appropriate counteractive drugs.

Persistent Tardive Dyskinesia—As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movement of the tongue, face, mouth, or jaw (eg, protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and if the medication is stopped at that time the syndrome may not develop.

Cardiovascular Effects: Tachycardia, hypotension, hypertension, light-headedness, and syncope have been reported.

A few cases of ECG changes similar to those seen with phenothiazines have been reported. It is not known whether these were related to loxapine administration.

Skin: Dermatitis, edema (puffiness of face), pruritus, and seborrhea have been reported with loxapine. The possibility of photosensitivity and/or phototoxicity occurring has not been excluded; skin rashes of uncertain etiology have been observed in a few patients during hot summer months.

Endocrine Effects: No endocrine abnormalities have been reported.

Anticholinergic Effects: Dry mouth, nasal congestion, constipation, and blurred vision have occurred; these are more likely to occur with concomitant use of antiparkinson agents.

Other Adverse Reactions: Nausea, vomiting, weight gain, weight loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, and polydipsia have been reported in some patients.

DOSAGE AND ADMINISTRATION

LOXITANE *loxapine succinate* is administered orally usually in divided doses two to four times a day. Daily dosage (in terms of base equivalents) should be adjusted to the individual patient's needs as assessed by the severity of symptoms and previous history of response to antipsychotic drugs. Initial dosage of 10 mg twice daily is recommended, although in severely disturbed patients initial dosage up to a total of 50 mg daily may be desirable. Dosage should then be increased fairly rapidly over the first seven to ten days until there is effective control of psychotic symptoms. The usual therapeutic and maintenance range is 60 mg to 100 mg daily. However, as with other antipsychotic drugs, some patients respond to lower dosage and others require higher dosage for optimal benefit. Daily dosage higher than 250 mg is not recommended. For maintenance therapy, dosage should be reduced to the lowest level compatible with symptom control; many patients have been maintained satisfactorily at dosages in the range of 20 mg to 60 mg daily.

HOW SUPPLIED

LOXITANE *loxapine succinate* is supplied in the following base equivalent strengths:

CAPSULES Hard Shell Printed "Lederle"

10 mg—Green and Yellow; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5360.

25 mg—Green Two Tone; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5361.

50 mg—Green and Blue; Bottles of 100, 1000, and unit dose 10 x 10's—Product Number 5362.

For Brief Summary, please see following page.

SANDOZ

75-379

RESULTS OFTEN SEEN IN A WEEK

Because the somatic and psychic complaints that accompany depressive neurosis can interfere with the treatment of the underlying psychopathology—rapid relief of these symptoms is often crucial to therapy.

In 14 double-blind studies of four weeks duration, 339 patients with depressive neurosis received Mellaril. In these studies, 55% of the overall improvement was observed by the end of the first week, and a total of 293 patients (86%) improved during the four weeks.*

Mellaril usually does not cause euphoria or undue sedation and is nonaddicting. Patients, therefore, generally remain alert and better able to respond to therapy. (The physician should, however, caution patients against participating in activities which require complete mental alertness, e.g., driving.)

*Data on file at Sandoz Pharmaceuticals.

MELLARIL®
(THIORIDAZINE)

TABLETS: 25 mg and 50 mg thioridazine HCl, U.S.P.

for the short-term treatment of moderate to marked depression with variable degrees of anxiety in patients with depressive neurosis

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg. should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling. The following reactions have occurred with phenothiazines and should be considered: *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient. In adults with depressive neurosis the usual starting dosage is 25 mg t.i.d. and the dosage ranges from 10 mg b.i.d. to q.i.d. in milder cases to 50 mg t.i.d. or q.i.d. for more severely disturbed patients; the total daily dose ranges from 20 mg to a maximum of 200 mg.

THE AMERICAN JOURNAL OF PSYCHIATRY

The Current Status of Behavioral Psychotherapy: Theory and Practice

BY ISAAC M. MARKS, M.D., D.P.M.

Behavioral psychotherapy has become one of the definitive treatments available for the relief of psychiatric suffering. Although hardly a panacea for all ills, the behavioral approach is the treatment of choice for certain selected problems. Behavioral methods make their contribution in the context of general psychiatric management and often must be used in conjunction with other treatment. The theoretical and practical aspects of behavioral psychotherapy have changed a great deal over the past few years and continue to evolve rapidly. Although useful molecular theories are emerging to guide the discipline, no global theory is likely to be satisfactory in the foreseeable future.

THE PRINCIPLES OF behavioral psychotherapy reach back over the centuries. The ideas that govern the behavioral treatment of anxiety were enunciated clearly in the 1650s by John Locke. He recommended that if "your child shrieks and runs away at the sight of a frog, let another catch it, and lay it down at a good distance from him: at first accustom him to look upon it; when he can do that to come nearer to it, and see it leap without emotion; then to touch it lightly, when it is held fast in another's hand; and so on until he can come to handle it as confidently as a butterfly or a sparrow" (1, pp. 481–482). Today this principle is called exposure in vivo, and we could thus say that behavioral theory is Lockean in origin. It could also be said to be Freudian if one goes by Freud's comment in 1919: "One can hardly master a phobia if one waits till the patient lets the analysis influence him to give it up . . . one succeeds only when one can induce them by the influence of the analysis to . . . go [about alone] . . . and to struggle with their anxiety while they make the attempt" (2, pp. 165–166).

Another behavioral principle, that of satiation, is described in Shakespeare's opening lines of *Twelfth Night*: "If music be the food of love, play on; . . . that, surfeiting, the appetite may sicken, and so die." The concept of contingent reward dates back to the first parent who gave his child a candy or a kiss for good behavior.

The fact that the principles of behavioral treatment have been around so widely for so long indicates that they are rooted in common sense, which is as old as the human species. What, then, is new? The answer is that these commonsense principles have been welded together over the past two decades into a potent therapeutic technology that can now relieve several formerly untreatable conditions and holds promise for further advances. This development hinges on combining an experimental and a clinical approach. It enables treatment to be tested and refined so that redundant elements are gradually eliminated while effective ingredients are retained and extended.

This pragmatic approach reminds one of a legendary South African millionaire who was confronted with some awkward facts about his policies at an annual meeting of the board of his company. He faced his inquisitors squarely, thumped his fist on the table, and declared, "Gentlemen, those are my principles, and if you don't like them, I have many more."

Critics might call this theoretical promiscuity or gutless eclecticism. Progress, however, depends on keeping track of the main question facing clinicians: "What methods of treatment produce reliable improvements in problem X, and what principles govern such successful methods?" In short, what works and why? Advances can be rapid if we keep this question in mind and maintain a willingness to submit our ideas to ex-

Revised version of a special lecture presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Marks is Reader in Experimental Psychopathology, Institute of Psychiatry, the Maudsley Hospital, De Crespigny Park, Denmark Hill, London, SE 5, England.

perimental destruction. Inert therapeutic practices can thus be discarded and more potent methods introduced.

It is true that the behavioral field, like any other, has had its fill of dogmas. There has been no shortage of all-explanatory schools, each trimming the richness of clinical experience to its own Procrustean formula in the name of ideological purity. But the clash of rival parties becomes more muted as the area of tested knowledge expands. Behavioral treatment is beginning to take its place as one of several forms of psychotherapy available to the clinician for the relief of psychiatric suffering. Behavioral psychotherapy is not a panacea or an all-embracing theory or method. Like psychopharmacology, it is a therapeutic technology that can aid general clinical management and has its indications and contraindications.

INDICATIONS FOR BEHAVIORAL PSYCHOTHERAPY

There is no danger of a takeover bid by behaviorists for the whole of psychiatric practice. At the present time behavioral psychotherapy can help perhaps 10% of all *adult* psychiatric patients when used as the chief instrument of change. This means that 90% of all adult cases require other approaches as the main form of treatment. Behavioral psychotherapy is probably the *approach of choice* in phobic disorders, including social anxieties, and in obsessive-compulsive rituals. It is also helpful in sexual dysfunctions such as impotence and frigidity and in sexual deviations such as exhibitionism. In these areas behavioral methods have been found to be more useful than contrasting approaches.

In other adult disorders behavioral psychotherapy may be useful, but more controlled data about efficacy are needed. Examples include obsessive thoughts (as opposed to rituals); deficits and problems in social skills; disorders of habit or of impulse control such as stammering, hair pulling, self-mutilation, and compulsive gambling; appetitive disorders including obesity and anorexia; conversion hysteria; and some personality disorders. An operant approach can be helpful for the social rehabilitation of persons with certain chronic disorders such as schizophrenia and personality and organic deficits. In such cases the behavioral approach can be a worthwhile adjuvant to other treatment methods.

In several important adult disorders behavioral psychotherapy is *not of value*. Examples are acute schizophrenia, severe depression, and hypomania. This approach is also not useful in adult neurotic patients for whom clearly definable goals cannot be worked out.

In children behavioral psychotherapy might be the treatment of choice for nocturnal enuresis and phobias. It is also helpful for the educational rehabilitation of children with subnormal intelligence or learning problems. It has also been useful in institutional settings for the rehabilitation of delinquents, although backup facilities are a problem. Anecdotal reports suggest that behavioral therapies are sometimes useful in treating conduct disorders in children.

Until recently much of the evidence for behavioral psychotherapy fell far short of the ideal, i.e., controlled studies of groups of patients with clearly definable characteristics who were treated by either a behavioral or a contrasting method. Data were originally based primarily on uncontrolled case histories or on controlled trials of volunteers (3, 4), who may differ from patients in important ways. However, an increasing number of controlled trials of clinical patients is beginning to support the value of some behavioral methods.

Behavioral approaches are being applied increasingly not only for the relief of psychopathology, but also in educational, social, and other nonclinical settings. At certain points interventions with patients can be said to lie more in the domain of the educationalist and social psychologist than that of the clinician. However, this report is concerned only with behavioral psychotherapy in the field of clinical psychiatry and will not go into wider areas of behavior change.

PRINCIPAL FORMS OF BEHAVIORAL PSYCHOTHERAPY

Behavioral methods assume diverse forms, some of which bear little resemblance to one another. A cynic might argue that those methods which are found to be effective tend to be called behavioral and those which are not are disowned and given some other name. Often the same technique is practiced by adherents of different schools. A case in point comes from Viktor Frankl (5, 6), who attributed his ideas to existentialist logotherapy. In the treatment of an obsessive-compulsive ritualizer he described how he demonstrated to the patient that he could dirty his own hands by touching the floor and refrain from washing thereafter; then he asked the patient to imitate the same action. Behaviorists might call this modeling with exposure in vivo and response prevention. But we need not quibble about theoretical pedigrees. It is more important to describe our methods so that others can test and use them in a similar way.

Behavioral treatments can be administered to patients individually or in groups, depending on what is practical and desirable in a given case. Behavioral treatments can be arbitrarily divided into those which 1) reduce anxiety-linked behavior (e.g., phobias or compulsive rituals), 2) reduce appetitive behaviors (e.g., exhibitionism or obesity), and 3) develop new behavior (e.g., teaching social skills to the socially incompetent).

Anxiety reduction is usually effected by some variant of exposure treatment such as desensitization or flooding; self-regulation and modeling can also be useful. Appetitive behavior can be reduced by self-regulation, satiation, and aversive methods such as covert

sensitization. In covert sensitization, for example, an exhibitionist might be asked to imagine exposing his genitals to a pretty young girl in the street and then to imagine a policeman at his side arresting him. The fantasy of the policeman acts as an aversive stimulus. Equally, the exhibitionist could be asked to wear an elastic band on his wrist wherever he went, and when he felt an urge to expose himself, simply to snap the elastic band sharply against his wrist, repeatedly if necessary, until the temptation disappeared. This can be construed as a form of self-regulation as well as aversion. It could also be called thought-stopping. One patient I saw had morbidly jealous thoughts about his wife. After a few trials with the elastic band, he found it sufficient simply to stare at the band on his wrist and imagine the sensation of a sting on his wrist without actually snapping the band. Anticipation of the sting dispelled the jealous thoughts. He remained well at 6 months' follow-up after only 3 sessions of treatment.

These examples illustrate how the same technique can be described and used in several different ways. The elastic band can be an aversive stimulus, a thought-stopper, a self-regulator, or a response-disruptor.

A variety of methods is employed for the development of new behavior, including social skills training, educational programs, modeling, shaping, prompting, pacing, fading, self-regulation, contracting, and contingent reward. In social skills groups there is a great deal of overlap with techniques also found in psychodrama and encounter groups, e.g., warm-up games, role rehearsal, role reversal, and doubling. The same can occur in groups for family and marital therapy. These approaches are strictly behavioral only to the extent that they are directive and involve clearly specified goals of treatment and measurements of change.

GENERAL ISSUES

Certain general principles run across the arbitrary subdivision of behavioral methods. *Clear delineation of treatment goals* is essential. Often these are called target problems. If the behaviors to be changed by the end of successful treatment cannot be identified, then the patient is untreatable by behavioral means. Clear targets need to be set toward which treatment is directed. "Self-actualization" would be too vague to be a suitable target; so would "increased self-confidence." Examples of clear targets are "being able to ask a girl for a date without trembling" and "being able to shop in a crowded supermarket." Several targets are commonly needed for each patient. Targets must be specific and useful for a patient in terms of his life handicap.

Cooperation of the Patient

Behavioral treatment can only be given to adult neurotics if they are cooperative; successful treatment cannot be forced on patients against their will. Treatment often involves the patient in detailed, complex programs that require his daily cooperation for completion.

Family Involvement

Significant family members must participate in therapy when the patient's psychopathology is hindering family functioning. Treatment often needs to be continued away from the psychiatrist's office in the natural setting of the problem, which frequently includes the patient's home. Patients with social phobias may need to accompany a behavioral psychotherapist into a crowded restaurant and have a meal with him several times in order to overcome their anxiety. A compulsive handwasher may need to visit her home with her therapist and jointly contaminate the home with "dirty" material and refrain from washing thereafter. These unconventional roles may require some relearning experiences by therapists.

Backup Facilities in the Community

Backup facilities in the community are often required. Patients may need to be discharged to a residential treatment facility or other accommodation where treatment and supervision can gradually be "faded out." When the patient lives far from the treatment center, local personnel may be essential to provide necessary follow-up treatment after discharge.

Homework by the Patient Between Sessions

Another important issue concerns homework assignments and practice in self-regulation. Patients may be given set tasks to perform between sessions, and, indeed, the sessions may be contingent upon patients completing their homework first; e.g., a person with a social phobia may need to take his girlfriend out to a restaurant three times between two given sessions. Self-regulation may take the form of keeping a diary, monitoring and rating one's anxiety in phobic situations, practicing deep-breathing exercises during them, and learning to remain in the same spot until the anxiety has abated, which might take an hour or more.

It is usual practice to combine more than one therapeutic principle in the treatment of a given patient, as the occasion demands. The following example illustrates this.

Case 1. Jill was an 18-year-old girl with borderline intelligence and mild cerebral palsy. She had complicating chronic agoraphobia, compulsive handwashing, and frequent temper tantrums at home. The nurse-therapist treated Jill by first escorting her on walks outside the outpatient department for increasingly long distances, fading himself out of the situation, and persuading Jill to do the same exercises herself both during the session and at home between sessions. Between sessions Jill was asked to undertake increasingly long bus trips and to enter her achievements in a diary. The agoraphobia rapidly improved.

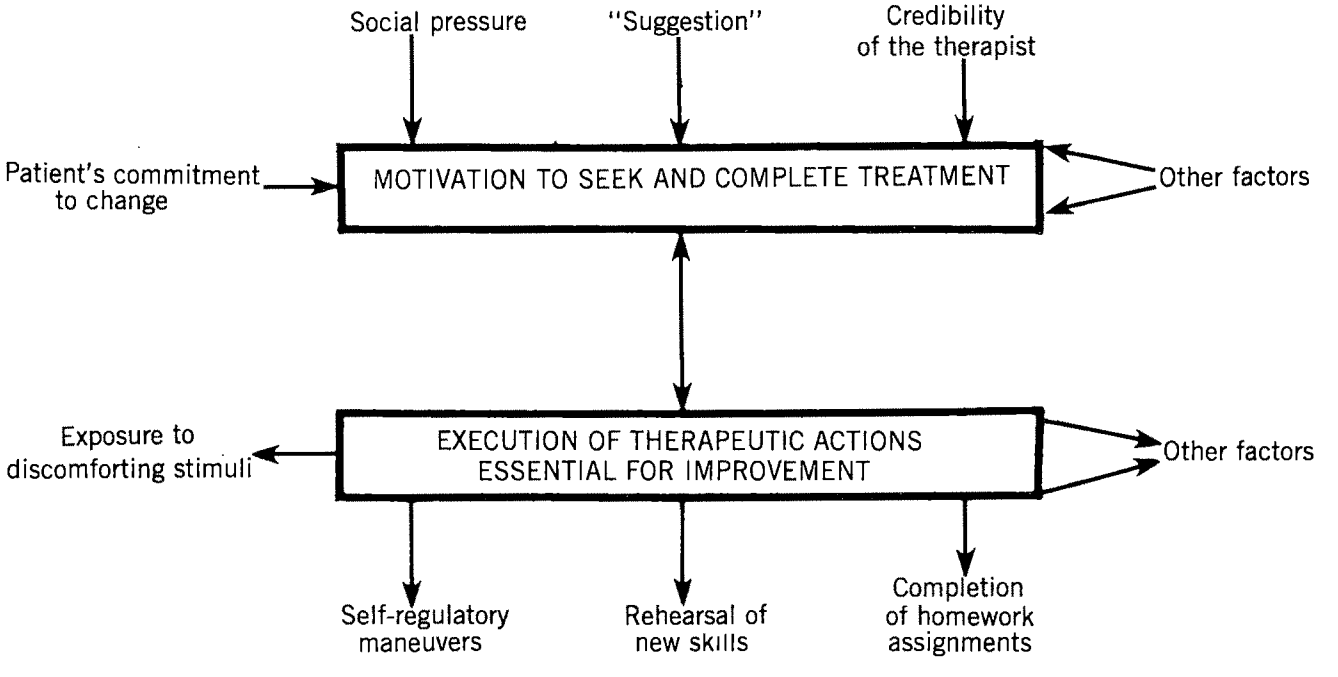
At the beginning the nurse-therapist had told Jill and her mother that he would leave the compulsive rituals for treatment at a later date when the agoraphobia had improved. The mother inquired about the nature of that treatment, and

the nurse-therapist explained the principles of exposure in vivo. By the time the agoraphobia had improved, the mother reported that she had spontaneously carried out the exposure in vivo treatment of her daughter's compulsions. She contaminated the house with dreaded material and asked Jill to do the same and refrain from washing thereafter. The patient's ritualistic behavior ceased when the mother acted as a cotherapist without the therapist's assistance.

The temper tantrums were dealt with by family contracting. The therapist jointly interviewed Jill, her mother, and her father and arranged an exchange of contracts whereby the parents agreed to lavishly praise their daughter for such behavior as helping at mealtimes to set and clear the table and wash the dishes. Jill promised to carry out such activities and not to engage in temper tantrums. Soon the temper tantrums ceased and the parents rewarded their daughter more often. At one-year follow-up Jill's improvement in her phobias, rituals, and temper tantrums continued and she was attending a special training course to develop work skills.

AN OPERATIONAL FRAMEWORK FOR THERAPEUTIC INFLUENCES

The many influences that bear on treatment can be viewed within a dual-process operational framework (see figure 1). First, a patient needs to be *motivated* to seek and complete treatment. Many influences will affect this process, including the patient's own commitment to change, social pressure on him to improve, that vague element called suggestion, and the credibility of the therapist. Of several hundred patients in my unit who were offered behavioral treatment, 23% refused it. This refusal rate is similar to that with many other treatments. In such cases treatment fails at the motivational stage because the patient fails to swallow his psychological pill, so to speak. Most behavioral treatments are, in fact, readily acceptable to patients.



The second process involves the patient's *execution* of therapeutic actions essential for improvement, e.g., a few hours' exposure to a phobic stimulus or a complicated set of interactions with other people in a social training program. When execution of these actions is satisfactory, the failure rate is very low in phobic and obsessive-compulsive patients.

APPROACH TO PHOBIC AND OBSESSIVE-COMPULSIVE DISORDERS

Let us examine the principles and results of behavioral psychotherapy in two extensively studied syndromes—phobic disorders and compulsive rituals. Most behavioral approaches to their treatment employ a common principle called *exposure*. The concept of exposure holds that relief from phobias and compulsions comes from the individual's continued contact with the situations that evoke his discomfort. Clinicians need to search for those cues which trigger phobias and rituals and to confront the patient, given his agreement, with these cues. The principle of exposure does not explain why improvement occurs under these conditions.

Several controlled trials with phobic and obsessive-compulsive patients have shown that exposure treatments produce significant improvement in phobias or compulsions up to the latest 2- to 4-year follow-ups that are available. These results can be obtained with

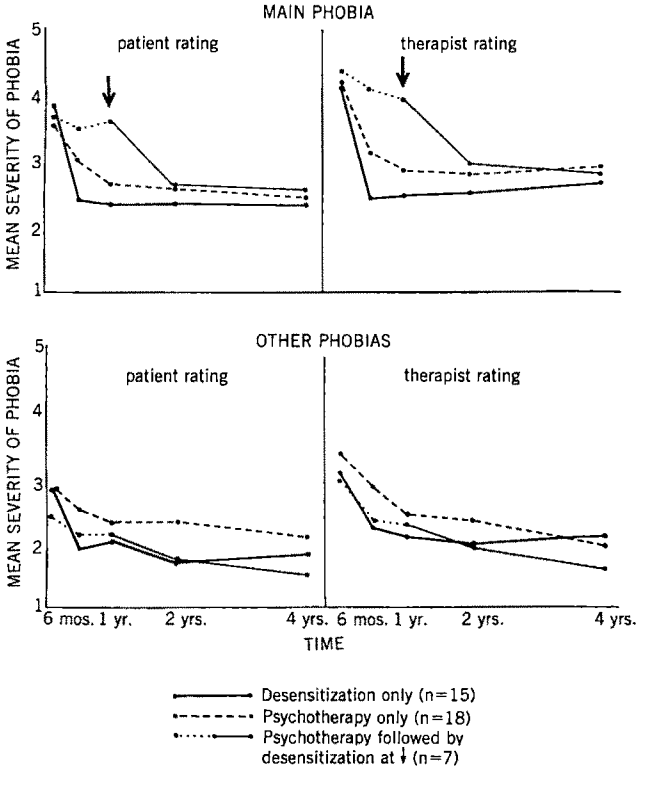


FIGURE 1
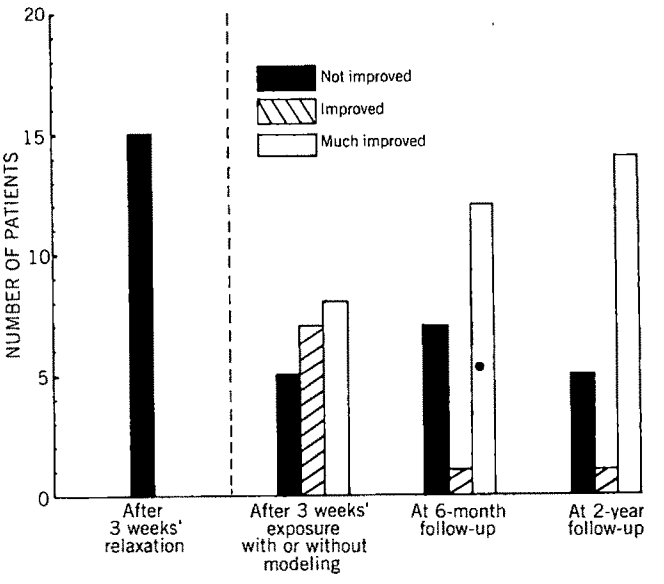
Therapeutic Influences: An Operational Framework

real-life exposure after 1 to 30 sessions. The last 100 patients treated in my unit required a mean of 11 treatment sessions. The more complex problems with wider ramifications require longer treatment. Chronicity of illness, however, is not important; even long-standing problems can be relieved in a few hours of treatment.



An early form of exposure treatment was Wolpe's (7) desensitization in fantasy, in which the patient is relaxed and asked to repeatedly imagine himself gradually approaching the object that causes him fear. Phobic images are visualized only for a few seconds at a time, and the subject is asked to relax between images. In an early series of trials by Gelder, Marks, and Wolff (8–10), desensitization in fantasy reduced phobias more than dynamic psychotherapy (see figure 2). Patients who did not improve with psychotherapy were given desensitization in fantasy, which reduced their phobias. The superiority of desensitization was gradually eroded as other patients similarly improved over the years, but subjects receiving desensitization improved earlier and with less treatment and maintained their improvement at 4-year follow-up (11) (see figure 2).

FIGURE 2
Improvement in Phobic Patients with Desensitization and Psychotherapy*

*Based on material from Gelder and associates (8) and Gelder and Marks (9). Reprinted by permission from "Phobic Disorders Four Years After Treatment: A Prospective Follow-Up," by I.M. Marks, *British Journal of Psychiatry*, volume 118, pages 683–688. Copyright 1971, the Royal College of Psychiatrists.

FIGURE 3
Improvement in Obsessive-Compulsive Patients with Exposure in Vivo and Relaxation*

*Reprinted by permission from "Treatment of Chronic Obsessive-Compulsive Neurosis by *in-vivo* Exposure: A Two-Year Follow-Up and Issues in Treatment," by I.M. Marks and associates, *British Journal of Psychiatry*, volume 127, pages 349–364, 1975. Copyright 1975, the Royal College of Psychiatrists.

These results were replicated by Gillan and Rachman (12) in a similar group of phobic patients. They found that desensitization in fantasy was superior to dynamic psychotherapy for the relief of phobias and that improvement continued to 3 months' follow-up. The amount of improvement with each treatment was comparable to that obtained in the earlier investigation.

More recently, emphasis has been on exposure in vivo. This gives quicker results by bringing the patient into contact with his discomforting situation without the relaxation exercises. A partially controlled experiment (13) showed that exposure in vivo improved obsessive-compulsive rituals significantly more than did relaxation treatment (see figure 3). In a subexperiment, patients who had exposure in vivo without preceding relaxation did just as well as those whose exposure followed relaxation. Improvement with exposure in vivo thus occurred whether it was given as the first or second treatment block (14). Improvement continued to 2-year follow-up (see figure 3).

EXPOSURE TREATMENT

Varieties

Exposure treatments come in many forms. To illustrate these, let the reader imagine a man with a height phobia quivering at the foot of a 20-foot ladder. His aim is to climb to the top of the ladder to retrieve a book titled *How To Overcome Your Fear of Heights*.

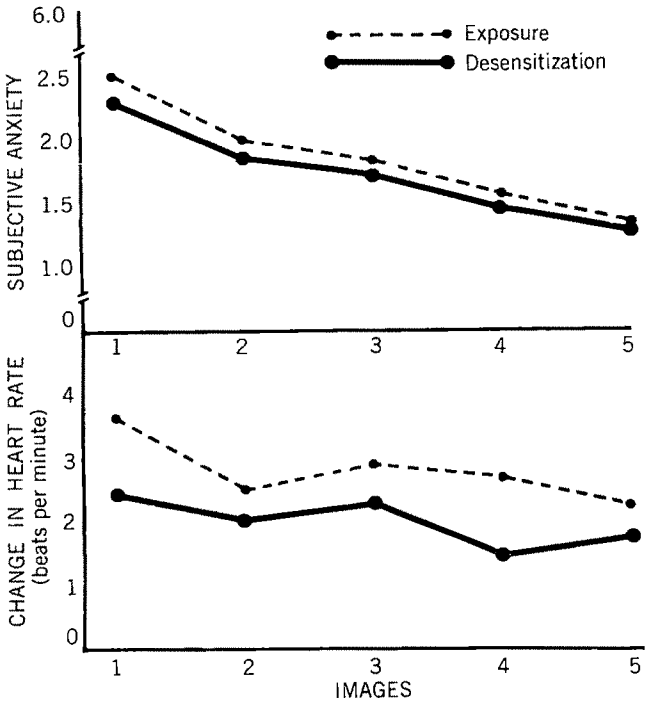
In this therapy many options are open. We can ask him to close his eyes, relax, and imagine himself slowly putting his foot on the first rung of the ladder and then relaxing again, and to imagine this several times until that inspires no anxiety, after which he can imagine himself on the second rung of the ladder, etc. That is *desensitization in fantasy*. If we asked the patient to carry out the same maneuvers in real life rather than in fantasy, that would be *desensitization in vivo*.

An alternative strategy would be to ask the patient to close his eyes and imagine himself standing right at the top of the ladder looking down, swaying, and feeling dizzy and scared at the same time, and to continue to imagine this until he feels better. This is *implosion* or *flooding in fantasy*. The *real-life flooding* variant would be (with his permission) to grab him by the scruff of his neck and thrust him to the top of the ladder and keep him there, sweating out his fear, until he becomes used to the situation. If for any of these procedures we first demonstrate to the patient what to do, e.g., if we precede him up the ladder, we would call this *modeling*. If we praise the patient each time he takes a step up the ladder this is *operant conditioning* or *shaping*. If we ask the patient to close his eyes and imagine himself persuading another patient with a height phobia that it is good for him to go up the ladder, this would be *cognitive rehearsal*. If the patient is asked to say to himself, "This is not so bad, I can really tolerate this fear"—that is *self-regulation*.

The Exposure Principle

These and many other techniques are called by a bewildering array of confusing terms. There is a natural tendency to seek a single explanatory principle behind diverse treatments, although reality is usually more complex than our constructs. A therapeutic element more pervasive than most in all the methods described for getting the height phobic up the ladder is that of exposure to a noxious stimulus until he becomes used to it. Alternative terms for "becomes used to it" are habituates, extinguishes, or adapts, each of these terms having overlapping implications. The noxious stimulus may be a troublesome fantasy, a feeling of uncertainty about the future, an airplane flight, or sexual intercourse. It is not my brief to discuss how such stimuli come to be perceived as noxious in the first place. However, once situations repeatedly produce discomfort, as in phobias and obsessions, then sufferers usually lose this discomfort by agreeing to remain exposed to those situations until they feel better about them.

Exposure is a similar concept to extinction. "Extinction" simply means that the response ceases to occur, without explaining why. Similarly, the concept of exposure simply holds that given enough contact with the provoking situation, the phobic or obsessive person ceases to respond with avoidance, distress, or rituals. Patients rarely become sensitized to a situation through clinical exposure. Unfortunately, we do not know what causes such sensitization, a reaction that has important theoretical implications. The problem is why 3% fail to improve at all, rather than a problem of relapse, which is a different but not a serious issue. The question is why exposure to a trauma sometimes produces phobias and at other times cures them. Which sets of conditions predict a traumatic or a curative outcome must still be delineated, but systematic research has begun to chart some dimensions of this problem.



Low Anxiety

Wolpe has suggested that relaxation or other procedures are necessary to "reciprocally inhibit" anxiety during contact with the phobic stimulus, in order that improvement can follow. Many experimenters since then have found that the outcome to desensitization in fantasy is not impaired by omitting relaxation; the evidence points strongly to relaxation's being a redundant element in the therapeutic package (4). An example of an experiment that disconfirms the idea of reciprocal inhibition comes from Benjamin and associates' work (15) with chronic phobic patients. In a controlled study these patients imagined phobic images up a hierarchy while they were either relaxed or in a neutral affective state. The hypothesis of reciprocal inhibition predicts that relaxed subjects will show less anxiety to phobic images during treatment and have a superior outcome in reduction of fear.

The experimental manipulation was successful in producing two significantly differentiable treatment conditions. During treatment sessions relaxed patients had significantly less skin conductance activity between phobic images than did patients who had not been relaxed, i.e., they were less aroused. However, contrary to prediction from our reciprocal inhibition model, arousal between images during treatment did not correlate with decreased anxiety either during or after treatment. Relaxation did not increase the speed with which patients lost their fears during sessions and did not increase the extent of improvement at the end of treatment. During sessions, subjective anxiety and heart rate diminished at the same rate whether the phobic images were visualized during a state of relaxation (desensitization) or neutral affect (exposure) (see figure 4). After the end of each treatment condition the reduction in phobias was similar. This result was replicated by Gillan and Rachman (12), who found comparable outcomes in phobic patients after treatment by desensitization in fantasy with and without accompanying training in muscular relaxation. One can thus conclude that training in muscular relaxation exercises can be omitted from exposure treatment without impairing results.

Thus far I have dealt with relaxation accompanying exposure treatment. Relaxation without exposure is also not helpful. Rachman and associates (13, 14) found that compulsive rituals did not improve after 15 sessions with muscular relaxation but were reduced significantly after 15 sessions of exposure in vivo (see figure 3). These findings were subsequently replicated in a

FIGURE 4
Change in Heart Rate and Subjective Anxiety With Successive Presentations of Images During Desensitization in Fantasy With and Without Relaxation*

*Reprinted by permission from "Active Muscular Relaxation in Desensitization of Phobic Patients," by S. Benjamin and associates, *Psychological Medicine*, volume 2, pages 381–390. Copyright 1972, the British Medical Association.

study by Roper and associates (16). In fact, relaxation is such an inert factor in the treatment of phobias, compulsions, and even sexual deviations that it can safely be used as a control to contrast with more active treatments under investigation (17).

High Anxiety

A view opposite to that of reciprocal inhibition is the notion of implosion (18). The concept of implosion holds that for improvement to occur, anxiety must be maximally aroused during exposure until the patient is so exhausted that he cannot experience any more emotion. The evidence for this concept is based on uncontrolled clinical experience and can be paraphrased from Stampfl's comment about one obsessive-compulsive handwasher: "He who has lived in a cesspool for a few days [in his mind] will not worry later about a bit of dirt on his hands" (18).

The question is whether the deliberate evocation of anxiety adds to the therapeutic effect of exposure. Mathews and associates (19) found that high anxiety yielded no better results than low anxiety during fantasy exposure with phobics.

Whether high arousal facilitates in vivo exposure was tested by Hafner and Marks (20). Chronic agoraphobic patients were exposed continuously for 3 hours a day over 4 days to their real phobic situations, e.g., they were asked to shop in crowded supermarkets or to ride in subway trains until they felt better about being in these situations. In a high-anxiety condition the therapist commented on how bad the patients looked and mentioned all the catastrophes that might befall them in these situations. In a low-anxiety condition the therapist was reassuring, although he could not eliminate all anxiety. The experimental manipulation produced two significantly differentiable treatment conditions, with patients experiencing significantly more discomfort during exposure in the high-anxiety condition. However, this produced no difference in outcome on any measure. Low-anxiety patients improved at the same speed and to the same extent as high-anxiety patients. Thus anxiety did not facilitate improvement during exposure.

Further evidence that higher arousal is not especially helpful comes from a second controlled experiment by Hafner and Marks (20). In a double-blind study chronic agoraphobics were exposed as groups to their real phobic situations. Two groups of patients receiving diazepam reported less discomfort during exposure than patients receiving placebo, and they improved at the same rate as the placebo patients. Results from these studies of phobics are in line with findings from 3 earlier experiments that anxiety during exposure does not predict subsequent outcome in phobic patients (21–23).

In summary, phobias and obsessions improve with exposure treatment, but it does not matter whether patients are relaxed, neutral, or anxious during such exposure.

A more important variable is *duration of exposure*. In a Latin-square design, Stern and Marks (23) exposed chronic agoraphobics to flooding for long or short periods in fantasy and in vivo. Exposure in vivo gave significantly better results when carried out for 2 continuous hours rather than for 4 interrrupted half-hour periods in one afternoon. Long, continuous exposure was more effective in reducing heart rate during treatment sessions and in decreasing phobias at the end of treatment. Boulougouris and Rabavilas (24) replicated these results in obsessive-compulsive patients.

These experiments involved chronic patients, and the optimum time of exposure might well be less for those whose phobias are of more recent duration. Duration of exposure is presumably important because it gives certain unidentified processes more time to work while exposure is going on. For example, it might give people time to develop self-regulatory strategies to control their own emotions or to reach critical levels of habituation that may be necessary for lasting change to occur. The latter is implied in the question, "Is it best to end on a good note?" We have no answer as yet.

Fantasy Versus In Vivo Exposure

Another important variable is whether exposure is to the real or merely the fantasied situation. Re-

cent studies of volunteer phobics (4), agoraphobic patients (4), and obsessive-compulsives (24) have shown that phobias and rituals are reduced more efficiently by in vivo exposure. However, another study (25) failed to confirm this finding. The optimal strategy is probably to opt for in vivo exposure, using fantasy exposure only in special situations such as an unobtainable real phobic situation or a physical danger contraindicating marked anxiety, e.g., angina or severe asthma.

I have shown that what at first sight seem to be widely different forms of fear reduction—e.g., desensitization in fantasy, flooding in vivo, cognitive rehearsal, modeling, and operant conditioning—can all be subsumed under the rubric of exposure. The different names simply describe variations on the theme of exposure. The current treatment of choice for obsessive-compulsive and phobic disorders seems to be prolonged in vivo exposure of the patient to the noxious stimulus (with his consent). Response prevention may be yet another example of a treatment that finally works through exposure. In compulsive ritualizers, active prevention of the ritualistic behavior during exposure may be unnecessary except as a way of prolonging exposure, an idea supported in a pilot experiment by Lipsedge (26).

The principle of exposure to the stressful situation is important not only for phobias and obsessions but also for social deficits and sexual problems, although here it is bound up with training in interpersonal and other skills. In social skills training and in sexual retraining programs, of which Masters and Johnson pioneered one form, patients are required to rehearse appropriate behavior repeatedly in their problem situations until they lose their discomfort and acquire the requisite fluency of performance. In a controlled study of sexually dysfunctional patients, Mathews and Bancroft (27) found that one therapist was not significantly less therapeutic for a couple than a dual sex therapist team.

Shortcomings of the Exposure Model

The exposure hypothesis of fear reduction leaves several important facts unexplained:

1. A small minority of patients do not habituate during exposure despite their fulfillment of all criteria for predicted success, i.e., adequate motivation, absence of serious depression, no attempts to escape in fantasy or reality during exposure, and adequate duration of treatment. This is not a problem of relapse after improvement but rather the failure of any improvement at all. In these patients some crucial unknown factor for success is missing.
2. Some phobic, obsessive-compulsive, and other forms of anxiety improve with antidepressant drugs, without the need for any exposure.
3. Without any exposure to the specific phobic stimulus, anxiety sometimes remits after the abreaction of intense emotion, e.g., fear that is irrelevant to the phobic stimulus (22), anger (28), or other feelings.

A tempting explanation for the value of irrelevant fear might be that it teaches the patient a form of coping. This is a widening of the exposure hypothesis. It states that the patient benefits from exposure to irrelevant fear as he would to unpleasant emotions in general. This notion leads into muddy theoretical waters that are capable of experimental clarification.

The concept of coping with unpleasant emotions is related to that of stress immunization. It raises the possibility of preventing disorders by appropriate procedures in childhood and later periods. The idea was not new in ancient Sparta and amounts to the teaching of stoicism. Experiments with children (29) and students (30) indicate that this form of coping can be used in specific situations like visits to the dentist or pain in the forearm from ischemia induced by a pressure cuff on the arm. The question is to what extent stress immunization can be generalized, when it should be applied, in what way, for how long, and at what ages. We are only at the start of a long road of research into adaptive behavior.

DELIVERY OF BEHAVIORAL SERVICES

As behavioral treatments have been found to be effective for certain conditions, the demand for this therapy has greatly outstripped the supply of trained personnel. One possible solution is to produce new classes of therapists with shorter training than that required of doctors or psychologists. Operational research in this area has been successfully conducted in Britain. Given special training, psychiatric nurses working with patients with phobic, obsessive-compulsive, and sexual disorders achieved results as good as those of doctors and psychologists using comparable methods with similar patients (31).

The outcome of this work has been the development of an 18-month course, recognized throughout England and Wales, for the training of nurses in behavioral psychotherapy. These nurse-therapists act as the primary therapist in a therapeutic team while working with doctors or psychologists. This development greatly extends the number of patients who can be treated by a given team led by a doctor or psychologist. This is as true for private practice as for the public sector.

Many other classes of personnel have been involved in the administration of behavioral treatments for a wide variety of problems. More research is needed into possible models for the delivery of behavioral services in different countries. Such operational research might indicate improved ways of getting effective treatment to as many people as possible at a reasonable cost.

CONCLUSIONS

Behavioral psychotherapy is a vigorous growing point in psychiatric treatment. Several hitherto untreatable conditions now respond to behavioral treatment,

and it is at times a useful adjuvant for other problems as well. Behavioral psychotherapy is taking its place among the definitive treatments available for the relief of psychiatric suffering, and further advances in the field are appearing regularly. Although useful molecular theories are emerging to guide the discipline, no global theory is likely to be satisfactory in the foreseeable future. As always, as we learn to understand any area, the dialectic dance moves on to fresh ground.

The Psychological Treatment of Personality Disorder

BY PAUL C. HORTON, M.D.

The author presents three case reports of individuals with personality disorder, none of whom demonstrated significant ability for transitional relatedness before therapy. In therapy, he conceptualized for the two adult patients the importance of their inability to experience in the transitional mode; he offered concrete potential transitional objects to the one child patient. The therapeutic results were good.

"PERSONALITY DISORDER" is rigorously defined in the second edition of APA's *Diagnostic and Statistical Manual of Mental Disorders (DSM-II)*.

> This group of disorders is characterized by deeply ingrained maladaptive patterns of behavior that are perceptibly different in quality from psychotic and neurotic symptoms. Generally, these are life-long patterns, often recognizable by the time of adolescence or earlier. (1, pp. 41–48)

The detection of personality disorder in adulthood requires clear evidence of significant and long-standing interference with the ability to love and work (2); psychological testing may be necessary to ensure the absence of covert neurotic or psychotic conflicts (3).

My colleagues and I have suggested that the central obstacle to the use of conventional psychotherapies for patients with personality disorder is the inability of these persons to experience in the transitional mode (3). This ability is nearly universal in children (4), well-functioning adults, and, in my experience, individuals in all diagnostic categories except personality disorder. Within the category of personality disorder there appears to be no difference between *DSM-II* subtypes in the ability to relate transitionally—if any competence in this area is observed, it is rudimentary and inconsistent at best.

Essentially, transitional relatedness consists of the soothing blending of internal and external reality. Winnicott (5) suggested that this "intermediate" or "third" area of human experience is where vital human illusions are formed. We stated that this ability

> takes its origin, in part, from the time a child is able to imbue a toy or other concrete object with the life he feels stirring inside of himself . . . . Even as he recognizes that the teddy bear is indeed cloth, stuffing and buttons, he suspends that aspect of reality just enough to permit himself to ascribe to the object those traits and qualities he needs to see in himself at the moment. In this way, *that* teddy bear becomes *his* teddy bear. Unique in the world and irreplaceable, it is the psychological area of the personal universe where the external physical reality of cloth, stuffing and buttons becomes inseparably interwoven with the internal life of its owner. (3, p. 621)

Maturation entails increasing subtlety and complexity of transitional relatedness (3, 6, 7), which is exemplified by an adult's ability to be psychologically soothed through contemplation of religious ideas, artistic expressions, or the virtues of another person. Unfortunately, those with personality disorders do not show this ability with such tangible, concrete objects as the teddy bear, let alone with the more abstract elements of the human condition.

I have evaluated and treated many people with personality disorders. I could do nothing for those who demanded drugs to service an addiction, who wished to avoid the consequences of crimes, or who came only because the parole board insisted. Many personality disordered individuals are in unremittingly serious straits and come to a psychiatrist only during a legal crisis. This article does not concern the treatment of out-of-control, impulsively aggressive individuals but describes a particular psychotherapeutic approach potentially useful in an outpatient setting. In the three cases with well-defined personality disorder that I present here, the focus is on the importance of the therapist's awareness of the normal role of transitional relatedness in human interaction and on the way in which this may be translated into ideas the patient can employ. The internal psychological significance of this intervention has been discussed elsewhere (8, 9).

CASE REPORTS

Case 1. A 34-year-old divorced mother of three presented with depression. Her paramour of many years was leaving her for a younger woman, and she feared that loss of her youthful beauty would deprive her of finding a more permanent partner. She emphasized her need for economic security.

She described having been brutalized by many men. Her father, an alcoholic, was often violent and sexually seductive with his daughters. Her eldest brother raped her when she was 12 years old. Her husband also raped her and compelled their daughter to perform fellatio on him.

Dr. Horton is in private practice, 41 Mattabasset Dr., Meriden, Conn. 06450; he is also Assistant Clinical Professor of Psychiatry, Yale University, New Haven, Conn.

Curiously, all of the many men she dated after her divorce proved to be manipulative, selfish, cruel, alcoholic, and sometimes sexually perverse. The relationship that brought her to treatment was one of convenience. The man with whom she was involved raised her standard of living by supplementing her welfare benefits. In turn she permitted him the companionship of herself and her children. He demanded little of her sexually; she was glad of this because she did not particularly enjoy sexual intercourse. There was little sense of emotional intimacy, sharing, or support, and he often complained of her coldness.

There was no evidence of transitional object usage. She had never been playful and had had no favorite toys or attachments to stuffed animals, blankets, pillows, pieces of silk, dolls, music boxes, powder puffs, songs, nursery rhymes, prayers, or other common and potential soothers of children. She felt only rage and resentment toward her promiscuous mother and icy disdain toward her father. When he died, she mentioned it only parenthetically and never showed any indication of grief or mourning.

I treated her with psychoanalytically oriented psychotherapy for 85 hours over 2 years. There was a 2-month interruption of treatment after the first year when her growing positive feelings toward me proved too unsettling for her. During the first few weeks of treatment she ventilated resentment toward her departed paramour and the emptiness of her life. She expressed curiosity about my questions pertaining to toys and other special objects but appeared to attach little significance to this line of inquiry. Later, as she described her arid relationships with men, I commented: "It's difficult for you to let others soothe you." She replied that men wished only to exploit her sexually. The basis of her inability to sustain a heterosexual relationship came to light in the evolving transference: she was subtly seductive and simultaneously hostilely suspicious. Hers had too often been a self-fulfilling prophecy. She consistently undermined the essential humanity of those who tried to be close to her by responding only to their frailties and ugliness. She tried hard to convince me that she had no failings and nothing to learn. She was suspicious of my discreetness with her, reasoning that I must be a "cleverer" seducer than most. She experienced anxiety and despondency as it became clear that I had no intention of seducing her. After many months I was able to tell her that she had many assets, but there were some things she needed to understand: there were men who could genuinely love and give to her; she had to learn how to recognize and accept the goodness in others; and she could be soothed but she would have to learn how to experience this. We spent many hours on this issue vis-à-vis her children and a new male friend. Insight followed:

> I've been thinking about what you asked a long time ago regarding toys and special things. My oldest child had a blanket that she carried all over the place when she was a baby. My 13-year-old still has her blanket and loads of stuffed pets. My boy has his stuffed animal. But it is true—I've never been able to find relief in anything. Some people can smoke, drink, bite their nails, use drugs, gamble—I haven't even been able to do things like that. It seems that all I have ever been able to do is to see bad things in everybody, including myself.

She made considerable gains in her ability to accept psychological soothing. This was accompanied by greater warmth and openness toward me and efforts to relate more soothingly to her children and others. At the conclusion of treatment she had even begun to show interest in and concern for her mother.

Case 2. A 62-year-old accountant and father of three presented complaining that his penis was too short. He was desirous of intercourse with his wife but stated that "she couldn't care less." In recent months it seemed that she had grown contemptuous of him. Moreover, he was not on speaking terms with two of his children. He had never been able to enjoy his work. He and his wife shared few friends; he was known derogatorily as a perfectionist. He stated, "When I do something, I do it with an intensity that is unbearable." He also suffered from long-standing mucous colitis.

The patient had been abandoned to his "Germanically strict" grandparents when he was 4 years old. The only remembrance of a toy was that of a wind-up locomotive with which he had been struck on the head by a playmate. There were no stuffed animals, favorite blankets, good luck charms, or other common soothers in early life. He grew up in a "state of anticipation—a big problem all [his] life." He was always worried and expected to be punished for unintended misdeeds. He became a tough, self-sufficient person; he stated, "I was going to be the next bank president. I used to dream of sitting back behind a big desk directing people."

The evolution of transitional relatedness, which normally begins in early childhood, did not manifest itself until he was in his early forties. He described his first memorable psychologically soothing inner experience as follows:

> I was hard at work as usual. Muzak was on. "Ebb Tide" was popular in those days and they were playing it. As swamped with work as I was, I stopped to listen. It was kind of peaceful. One of the girls even commented on my listening. After that I'd always stop to listen to that piece. That tune and a couple of others provided a few minutes of relaxation, an inner quiet, as if floating on a cloud.

His rudimentary transitional relatedness soon became submerged, however, as he sought relief in alcohol. A physical sedative was substituted for nascent psychological soothing.

> I drank to get that inner quiet. Music was qualitatively more soothing. But it was too short. You can't listen night after night to a few tunes. Alcohol loosened me up. I'd come home with my stomach churning. I'd have a few drinks and that waiting pile of work would get further and further away.

After several years the patient joined Alcoholics Anonymous because, "Whatever soothing I got from alcohol had stopped. Drink was killing me. I was sick and getting sicker." Subsequently, he took a brief interest in religion but was not able to find emotional sustenance. Like the previous patient, he had no compensations—nothing to protect him from his growing sense of loneliness. As his wife became less sexually accessible, he turned to psychotherapy for the first time.

A thorough history of potential transitional object usage was elicited early in treatment. Significantly, he could not recall having experienced anything like an "inner quiet" vis-à-vis another human being, even during sex. I summarized this: "You seem to have trouble letting others soothe you." I also said that I believed he had been struggling to grow in this way since his early forties when he had first experienced an inner quiet with music.

> This focus proved useful. The following week he said: Last week's hour was the best yet. That damn teddy bear thing had never entered my mind. I used to think it was the other way around. In fact, there's something I'd better tell you about. My little granddaughter carries a blanket all over the place. I'm afraid to say that from time to time I've tried to take it away from her. My

daughter has been getting mad at me about this. I thought there was something wrong with her having it. Now it looks like it's me who's got something to learn.

The remaining sessions revolved around his need for mutually soothing relationships with other human beings. That this theme was beneficial and even itself soothing was confirmed by his parting remark: "Since coming here I've gone without Lomotil for the longest time in 10 years."

Case 3. A 9-year-old boy, the second of three siblings, was brought by his mother for psychiatric evaluation with the chief complaint, "We can't get him to go along with what we want." The incident resulting in referral was his threatening his older brother with a knife. His mother reported that "he always seemed to have a mean streak, was easily upset, and would have to get even for anything that [was] done to him." He had no history of transitional relatedness.

From the outset he sought to structure the hour's activities as completely and rigidly as possible. After many sessions during which he verbalized very little about himself, his family, school, or friends, I introduced, with some initial difficulty, a teddy bear and two dolls for play. He named the teddy bear Bruce and the two dolls Sam and Blackie. The patient spoke for Bruce, and I spoke for the dolls.

Bruce hit the dolls often. When they protested the hurt, he replied, "I have no feelings. I'm super. See, I can fly and twist my arms and legs in all directions." He challenged the dolls to hit him to prove that he had no feelings of hurt. They refused, stating that they had no desire to hit him. He persisted: "Come on! Hit me! I'll show you. Come on, I don't mind. Hit me." Sam demurred, asking him what it was like to be without feelings of pain. He said it was good, that without such feelings he could be super. He denigrated human beings, especially women, as weak because they had feelings. Sam and Blackie stated that they liked being filled with feelings of all kinds, that feelings made life rich. Bruce replied anxiously, "But, I'm stronger—see, I can turn my head all the way around." Blackie said, "Its good that you are strong. But I wouldn't trade my feelings just to be strong." Bruce then revealed that he was a "robot bear from outer space" and that it was impossible for him to have feelings.

In a subsequent session, Sam offered to hug Bruce to help him learn about human feelings. The patient reacted with acute agitation, put Bruce down, and said, "I don't like that hugging stuff." Returning to play, he mercilessly pummeled the dolls until they had to retreat from reach. They resumed play only on the condition that he not hit them. He broke his promise, however, and again forced the dolls to retreat under a barrage of blows. Finally, after several broken promises, the dolls withdrew and stated that they would not return that day. Bruce begged them to come back. They hesitated. He offered, "If you come back, I'll even hug you."

During the ensuing week, the patient suffered for several days from a headache that reached its apex on the day of the session. At the beginning of the therapy hour *he* eagerly initiated play with Bruce and the dolls. Bruce informed the dolls that he was the "old Bruce's twin brother." He explained that he had come in Bruce's place because Bruce was away seeing a "computer doctor." The doctor would fix Bruce so that "he [would] have feelings too." After a while the old Bruce reappeared and offered to hug the dolls as proof of his cure. The headache remitted but the "fixed" Bruce was worried. In order to be cured, he had had to give up his super strength. He was now merely strong. At home, improvements were noticed: he had begun snuggling up to his parents on the couch; he had discovered his siblings and had begun playing with them. His mother—an emotionally timid woman—was bewildered by his accusation, "You don't love me." The social worker explored ways in which the parents, especially the mother, might show more emotional accessibility and initiative. She was encouraged, for example, to kiss the patient goodnight even if he did not ask. After 6 months of therapy the attacks on the dolls had become infrequent. Bruce now protected the dolls from the school principal, creatures from outer space, and other menacing figures. The patient's growing fondness for Bruce and the dolls was paralleled by substantial improvement in his relationships at home, at school, with peers, and with me.

DISCUSSION

Even though they had not experienced other than rudimentary transitional relatedness, the adult patients had witnessed transitional object usage by others. The first patient saw that all of her children used blankets and stuffed animals, and the second patient had been troubled by his granddaughter's use of a blanket. My inquiries regarding their own experience in this mode made them aware of an important psychological difference between themselves and others. Therapeutically useful associations and insights followed. The first patient contemplated her lack of psychological compensations; the second patient recognized that he had yet to learn about a mode of relating that children exhibit spontaneously.

The child patient required a more concrete introduction to transitional relatedness. After a period of time, a vehicle for play and dramatization of conflicts (the teddy bear) became invested with fond regard. Correlative treatment of the parents was also attempted, and I suggested that the mother, in particular, become more soothing to the patient.

This evolving treatment technique has several steps: 1) the therapist must identify the inability to relate transitionally as a core ego deficit; 2) he must interpret this to the patient, calling on the latter's observation of transitional object usage by others and explain in nontechnical language its relevance to the patient's relationships; and 3) he must then help the patient to contemplate various interactions, the outcome of which depends on his ability to experience transitionally or to permit others to do so. The therapist thus *orients* the patient to perhaps the most basic ingredient in human interaction.

This educative approach is attempted in tandem with the therapist's efforts to create a soothing atmosphere. I did not, for example, discuss the adult patients' difficulties without acknowledging their assets. The therapist must constantly scrutinize the transference to eliminate painful, frightening, or hostile distortions of present reality; for example, I eventually acknowledged the first patient's unspoken expectation that I would ultimately sexually exploit her.

In conclusion, it is encouraging to see that transitional relatedness may be an ability whose acquisition by personality disordered individuals does not have a

terminal critical period as, for example, does language development. This observation has positive implications for the treatment of individuals with these disorders.

Psychosurgery: Some Current Observations

BY STEWART A. SHEVITZ, M.D.

The term "psychosurgery" encompasses a wide variety of different neurosurgical procedures applied in the treatment of behavioral and psychiatric disorders. Arguments about the effectiveness and ethicality of psychosurgery are often based on studies using outdated procedures or inappropriate patient populations. The debate over psychosurgery is also obscured by the frequent confusion between its use in classical psychiatric syndromes and in such controversial areas as aggression or violent behavior associated with temporal lobe epilepsy. The author believes that such factors need to be clarified so that practitioners can choose a personal position based on sound medical fact.

PSYCHOSURGERY IS one of the most complex, controversial, and misunderstood areas of psychiatry today. Even the name is controversial; some authors prefer the terms "psychiatric surgery" (1), "mental surgery" (2), "functional neurosurgery" (3), or "the surgery of the emotions" (4). Arguments on the merits and ethics of psychosurgery tend to be colored with emotionalism, offering antithetical viewpoints substantiated by references to a voluminous but contradictory literature. One can easily become bewildered by articles that range from severe condemnation of all forms of psychosurgery (5–7) to others espousing considerable enthusiasm (4, 8–13). This state of affairs, in combination with the notoriety that psychosurgery has gained from reports in the lay press, contributes to the rejection of psychosurgery out of hand by many psychiatrists.

The purpose of this paper is to offer the reader some guidelines with which to evaluate and put into perspective current efforts in the field.

I will focus primarily on the use of psychosurgery in the treatment of traditional psychiatric illness. This admittedly is discussing psychosurgery in a very restricted context, but one that may be most important to the practicing clinician. It is also a context frequently obscured by the debate over the use of psychosurgery in other behavioral disorders. The use of psychosurgery in more controversial areas such as aggressive behavior and violent behavior in association with temporal lobe epilepsy will be briefly touched upon.

One of the major difficulties in this area is that articles discussing different psychosurgical procedures, with different side effects, for various indications, and with various results are often lumped together indiscriminately when the merits of psychosurgery are debated. I will attempt to tease out some of these important variables that deserve individual attention.

TYPE OF PROCEDURE

In the 40 years since Moniz' first prefrontal lobotomy in 1936, a large variety of neurosurgical procedures have been employed in attempts to treat abnormal behavior. These include the standard lobotomy, transorbital lobotomy, cingulectomy, topectomy, gyrectomy, and bimedial leucotomy, among others (14). The frontal lobes have been assaulted by everything from scalpels to icepicks, from thermocoagulation to cryogenic probes, from radiation to ultrasound.

As Knight (15) has said, one can see in retrospect that procedures such as the standard lobotomy of Freeman and Watts were developed by clinicians who were perhaps over-eager following Moniz' demonstration that patients occasionally improved because lobotomy lessened the intensity of their emotional reaction to delusions or hallucinations. This was unfortunate because adequate physiological and anatomical studies of areas involved had not been performed. Hence, large areas of white matter were sacrificed in attempts to divide the unknown pathways involved. It was not possible to find specific areas in the prefrontal region responsible for clinical change following isolation or ablation. Clinical improvement and personality change appeared to correlate quantitatively with the amount of prefrontal cortex separated from its white matter. Marked blunting of the individual's personality and frequent surgical complications were undesirable side effects that occurred all too often with the early procedures (14, 15).

Recent evidence suggests that the beneficial effects seen following standard lobotomy might largely be at-

When this work was done, Dr. Shevitz was a resident in the Department of Psychiatry, Dartmouth Medical School, Hanover, N.H. He is now Chief of Psychiatry, Public Health Service Indian Hospital, Tuba City, Ariz. 86045.

The author gratefully acknowledges the assistance of Gary J. Tucker, M.D., in the preparation of this paper.

tributable to the disconnection of relatively discrete, functional areas of the orbital and medial frontal cortex from intermediate limbic circuits that lead to autonomic outflow pathways via the hypothalamus and brainstem (4, 15, 16). Efforts are now being made to attack these areas selectively to achieve therapeutic benefit without the adverse effects of inadvertent cutting of other fibers (4, 10–12, 17, 18). One example is the work described by Sykes and Tredgold (10). A form of orbital undercutting first developed by Scoville and Wilk (19) and modified by Knight (10, 20) is employed. By direct vision through burr holes, the orbital cortex (the ventral surface of the brain overlying the bony roof of the orbit and encompassing Walker's areas 13 and 14) is undercut at the junction of the white and gray matter. Such a procedure has a mortality rate of 1.5% and a postoperative epilepsy rate of 16% (well controlled by medication in most cases). Most importantly, only 5% of the 177 patients intensively studied by Sykes and Tredgold (10) were considered by them to have developed adverse behavioral effects following the operation, a marked improvement over the results of older procedures.

A further modification using radioactive yttrium implants stereotactically placed has also been developed by Knight (4). This procedure was originally thought to involve the substantia innominata; it is now termed a "stereotactic subcaudal tractotomy." In addition to a mortality rate of less than 1% from the operation, two reports reveal a postoperative epilepsy rate of only 1% to 2.2% (8, 9). Behavioral and psychological disturbances were lasting and troublesome in only 3% and 7% of the patients; 86% and 93% showed no undesirable symptoms at all.

These are but two examples of "modified" procedures. A number of other modified procedures involving cingulate and orbital regions have been described in the literature (11–13, 17, 18).

The important point to realize is that one must make distinctions between the various psychosurgical procedures before one can evaluate them. The standard open lobotomy that isolated 160 square centimeters of frontal cortex is markedly different from a stereotactic tractotomy in which only 8 square centimeters of orbital cortex (and possibly some fibers from the anterior cingulate gyrus) may be affected (4). Lesions produced in the cingulate or orbital regions do not appear to cause the severe emotional blunting or impairment of intellectual function that the older, more extensive procedures often did (4, 10, 18). Most practitioners concur that the detrimental effects of the standard lobotomy and its variants certainly outweighed the benefits (of which there were some) and have discarded these techniques. These techniques should be considered of historical interest only and not as evidence that subsequently developed procedures must invariably result in the same adverse effects. The difficulties with human heart transplantation did not invalidate all surgical approaches to the treatment of coronary heart disease. Similarly, the evaluation of current psychosurgical procedures should rest on their own individual merits and should not be judged by the adverse effects of their predecessors.

DIAGNOSTIC CATEGORIES

Much prefrontal surgery was originally aimed at schizophrenic patients before major tranquilizers were available (14, 21). Today schizophrenia should no longer be considered a prime indication for such procedures (8–10). Except when depression or severe anxiety are prominent, lobotomy has little to offer in acute or chronic schizophrenia and certainly cannot reverse chronic deterioration (14).

Psychiatrists often fail to recognize that many proponents of psychosurgery do not advocate this treatment method for schizophrenia. The best follow-up studies on psychosurgery from a psychiatric point of view are found in the British literature. Table 1 summarizes results from three such reports (8–10) mentioned previously. The table shows the number of patients out of the total patient population by diagnostic category who were either fully recovered or had only minimal symptoms following leucotomy. Follow-up occurred over a period of years following the operations. The best results were obtained with patients previously suffering from intractable affective illness. A number of patients with severe obsessional or anxiety neuroses also improved, although not as frequently as depressive patients. Results are also shown for the few schizophrenic patients operated on. When one considers the relatively intractable illnesses in this patient population, the results are noteworthy.

It is evident that although psychosurgery was originally employed extensively in treating schizophrenia, its effectiveness is now better evaluated with intractable depression, anxiety states, and obsessional neuroses. One is reminded of the history of imipramine, which was originally developed in the search for a better antipsychotic compound. Although it was found to

Göktepe and associates (9)	53 (78)	9 (18)	15 (24)	0 (4)

* Numbers in parentheses represent the total population of patients who received leucotomies.

be ineffective for psychosis, its mood-elevating properties in certain depressed patients were noted to be remarkable, and it has developed into one of our most effective antidepressant agents. The value of imipramine in treating depression is not invalidated by its ineffectiveness in treating schizophrenia. Similarly, psychosurgery's unsuitability for the treatment of schizophrenia today does not negate the possibility that it may be of value in other psychiatric disorders.

It is important to consider such factors when one is appraising a particular study from the literature on psychosurgery. Often, studies quoted as evidence against the efficacy of lobotomy (22, 23) have used a modification of the standard lobotomy procedure of Freeman and Watts or similar extensive procedures that cause broad lesions of variable extent and placement. Also, as pointed out by Post and associates (24), the subjects in many of these studies were hospitalized chronic schizophrenic patients. Such studies substantiate the fact that the older procedures are not of great value when used with schizophrenic patients, but these procedures and that patient population are not the areas in which psychosurgery is currently being investigated.

USE WITH BEHAVIOR DISORDERS

Psychosurgery, like many new treatment techniques, has been advocated for a wide variety of disorders. These have ranged from ulcerative colitis to drug addiction to hypochondriasis (14). Much of the current controversy regarding psychosurgery relates to its use with aggressive and violent behavior (6), particularly the treatment of temporal lobe epilepsy by amygdalotomy. This area has been well publicized in the lay press, especially the efforts of Mark and associates (25–27) to relate some forms of violent behavior to epileptic discharges in the amygdala. Such work is highly controversial and certainly has to be considered experimental at this time. The term "psychosurgery" is often applied to the lesions made in the amygdala to control the epilepsy that presumably is causing the violent behavior. Whether the behavior in question is actually secondary to the epileptic discharges is a subject of intense debate, as is the issue of side effects from this particular operation. Similarly, psychosurgical procedures are sometimes used to control behaviors that may or may not be considered "illness," for example, criminal behavior (6) and sexual deviations (28).

It is important to distinguish between the use of psychosurgery in these controversial areas and its use for such classical, well-defined psychiatric illnesses as involutional melancholia or severe obsessional neuroses. The controversy over a treatment modality such as psychosurgery should not be confused with the controversy over whether or not certain disorders for which it might be advocated are valid illnesses. The validity of psychosurgery should be considered with respect to its use in classical, clear-cut psychiatric syndromes accepted as disease entities by the medical community. One must have established the validity of the illness being treated before the efficacy of treatment becomes a meaningful question.

ABUSE OF PSYCHOSURGERY BY SURGEONS

A review of the world literature on psychosurgery quickly makes one realize that there is a wide variation in the indications and criteria that psychosurgeons use in choosing their cases (5). It would appear that not all employ the rigid standards of patient selection that would be demanded by many psychiatrists or by other surgeons. This should not, however, invalidate studies in which higher standards are met.

CRITERIA FOR PATIENT SELECTION

The current consensus seems to be that psychosurgery is not the treatment of choice for any psychiatric illness (14). The continuing debate centers on the fact that some practitioners do consider it a treatment of last resort in certain very specific cases. To be even considered for psychosurgery a patient should have proven to be unresponsive to all other appropriate psychiatric treatment modalities and he should be disabled to the point that any potential hazards from the operation are felt to be equal to or less than the disability suffered as a result of his illness. The probability of future remission without further treatment should also be considered nil (2).

Lehmann (29) has described his personal criteria for referring a patient for a psychosurgical procedure. He included the following criteria:

1. The disease should be a chronic tension state, anxiety, depression, or obsessive-compulsive disorder.
2. The patient should have a good premorbid personality.
3. The patient must have been disabled for at least two years.
4. Treatment by any of the following treatment modalities that were considered appropriate proved unsuccessful: a) psychotherapy by an experienced therapist for six months; b) antianxiety drugs such as chlordiazepoxide hydrochloride in doses up to 100 mg per day for at least two months; c) imipramine, 250 mg per day for six weeks; d) chlorpromazine, 1000 mg per day for two to three months; e) one or two courses of ECT (10 to 15 treatments per course); and f) a trial of lithium for one year if there is recurrent depression or bipolar illness.

Certainly every psychiatrist and surgeon would have his own modifications and additions for such a list; it is offered as an example of one person's opinion. It should also be recognized that there are many physicians who would not recommend psychosurgery under any circumstance.

ETHICS

The other major area of controversy regarding psychosurgery concerns the ethics and morality of such procedures. I will not address this very important issue at length because it is such an individual matter for each practitioner. The range of opinion is extremely diverse. One of the most prolific critics of psychosurgery, Breggin, considers such operations to be a horrible mutilation of man's highest function (5–7, 30). He abhors the idea of the frontal lobes being attacked in such a fashion because he feels they represent the seat of man's humanity. Others feel that an intractably ill individual who is terribly disabled by illness but can still voluntarily consent to such a procedure should not be denied the possibility of therapeutic benefit. In any event, one's position on this matter is probably not determined by rationality and deductive reasoning but rather by one's inner values and ethical interpretation of one's role as a medical practitioner under the Hippocratic oath.

CONCLUSIONS

One reason for the precipitous decline in the popularity of psychosurgery that followed the wave of enthusiasm it inspired in the late 1940s was the frequent complications—especially those involving personality changes—found with the more extensive procedures of that era. Another reason was the negative results of such comprehensive investigations as those of the Columbia-Greystone associates (31) concerning psychosurgery that involved selected partial ablation of the frontal cortex. Perhaps the most important factor in psychosurgery's fall from popularity was the advent of modern chemotherapy (major tranquilizers). It was the schizophrenic population—at which psychosurgery had been originally aimed—for which these new drugs were most effective.

Today the possible merits of certain psychosurgical procedures for some disorders have once again brought the area under intense public and professional scrutiny. Along with the formidable difficulties of clinical investigation, the problems of adequate control and criteria for patient selection are particularly difficult. In addition, it is known that adverse effects as judged by psychological testing may not become evident until 10 to 12 years after the surgery (32). The need for definitive studies to confirm the benefits reported and to answer the questions raised by critics is evident. Certainly such irreversible procedures deserve the severest scrutiny.

I have attempted to isolate some of the important factors that need to be weighed in evaluating the merits of this therapeutic modality. The purpose of this paper is not to advocate psychosurgery. It is a plea to every physician concerned with the subject to base his position on sound medical fact and practice. Only in this manner can we do proper justice to those working in the field. More important, only in this manner can the best interests of our patients be served.

Prompt Publication Policy

The *Journal* would like to remind authors who are particularly interested in early publication (whether to establish priority of an idea, reveal innovative results of new research, or for other pressing reasons) of its prompt publication policy. Under this policy, short (maximum of six double-spaced pages) manuscripts will be considered for publication in the Brief Communications section of the first available issue. These manuscripts must still undergo expert scrutiny before being accepted, and two months must be allowed for the printing process. However, the time required for publication of these short articles can be lessened considerably.

Authors who would like to have their manuscripts considered under this policy should indicate this desire, as well as the reasons for it, when they submit their manuscripts.

Services for the Aged in Community Mental Health Centers

BY ROBERT D. PATTERSON, M.D.

The author studied the services provided for the elderly at eight community mental health centers. He describes discrimination against the elderly, the reasons why relatively few elderly persons seek care, and innovations in treatment. He discovered that high-quality care depends more on staff awareness of the unique problems of the elderly than on specialized services. The author recommends a more public-health-oriented approach that would set priorities on the basis of community needs.

THE PURPOSE of this paper is to aid the program planning of mental health services for the elderly. The needs of the elderly have often been neglected by mental health programs. There has been little clinical research and very little research or discussion about program planning to meet their needs (1, 2). Two reasons for this neglect are negative attitudes toward the elderly and a false belief that most psychiatric conditions in the elderly are untreatable. The purpose of the survey reported here was to determine how community mental health centers are responding to the needs of the elderly.

Since the survey was conducted Congress has revised the community mental health center legislation (Public Law 94-63) to require a full range of "specialized" diagnostic, treatment, liaison, and follow-up services for the elderly in all federally assisted centers. Providing the required specialized services will, in most instances, not require segregating the elderly from patients of other ages. The legislation also provides a mechanism for consultation and education grants. If adequately funded, these grants can be especially beneficial to the elderly.

THE SURVEY

My associates and I visited 8 federally funded community mental health centers as part of a contract study for the National Institute of Mental Health. The centers were selected to provide a wide range of geographic locations and degrees of urbanization as well as a broad representation of communities with different ethnic, social, and age compositions. The sample may not be representative because centers with major organizational problems were excluded.

Each center was visited by 2 mental health professionals who spent 3 days in the area. Two days were devoted to obtaining information from persons not employed by the mental health center, such as welfare department and nursing home personnel and others familiar with the needs of the community. Elderly patients were interviewed, and in each area there was a meeting with at least one senior citizens' club or similar group. One day was devoted to interviews with staff members of the mental health center.

RESULTS OF THE SURVEY

Priorities

The primary orientation of the centers was to serve those who requested help. Since only a small number of the elderly asked for help, the amount of service given to them was small. There were few instances of a public health approach that set priorities on the basis of community needs. Thus the elderly were not given high priority.

Other factors also influenced the priority given to the elderly. In one case the community board asked the director of the center to give higher priority to the elderly. This request seems to have resulted from the experience of some of the board members with their own aged parents and from their awareness of the high proportion of elderly in the community. The possibility of earmarked federal funds to serve the mental health needs of the elderly had already stimulated some preliminary planning for improved programs.

Three of the centers gave special attention to the mental health needs of the aged. One had a full-time geriatric service coordinator (a social worker) and a small staff that provided direct service and consultation. Another center had a social worker with extensive experience in community development who devoted half of his time to planning, organizing, and coordinating services for the elderly. The third center provided staffing for a psychiatric unit in a nursing home. However, the unit was not prepared to provide intensive psychiatric care.

Having a specialized staff was not an indicator of the

Dr. Patterson is Lecturer on Psychiatry, Laboratory of Community Psychiatry, Harvard Medical School, 58 Fenwood Rd., Boston, Mass. 02115.

This work was supported in part by Alcohol, Drug Abuse, and Mental Health Administration contract HSM 42-72-197 from the National Institute of Mental Health.

The author wishes to acknowledge the participation of Drs. Frank Baker and Cecil Isaacs in this study.

priority given to the needs of the elderly, since some programs without specialized staff gave them appropriate attention.

Services

The centers differed widely in the policies and practices of their clinical services.

Inpatient services. All of the inpatient units admitted elderly persons. Most patients completed their treatment without transfer to a state hospital; direct admission to a state hospital was uncommon.

One inpatient unit admitted persons from nursing homes for brief treatment, most often for behavior problems that overwhelmed the nursing home staff. Behavior modification techniques were often used, and they seemed well suited to help many of these patients. Nurse consultants were available before admission and for follow-up.

In all, the patients we interviewed felt that they had received good care. Several who had experienced relapses after earlier hospitalizations praised the aftercare programs of the mental health centers.

It was evident that in many cases elderly patients received less adequate care than other adult patients. For example, one center, which often had a waiting list, required that the inpatient unit director approve the admission of all persons over age 65 who sought admission. Another center with a shortage of beds often sent elderly patients to a general hospital's extended-care facility rather than sending them to the psychiatric unit.

Although most state hospitals have screening procedures to reduce the number of inappropriate admissions, there were instances of patients being routed to bypass these procedures. Thus patients were admitted to state hospitals when admission to a mental health center would have been more appropriate. The staff of a state-operated geriatric screening unit, which interacted with several centers, reported that they had great difficulty in obtaining admission for geriatric patients.

When priorities for admission had to be set, it appeared that the elderly were likely to be given low priority.

Partial hospitalization. Among the centers visited, elderly persons were seldom referred to day care, although day-hospital programs have proved valuable for elderly patients (3).

Staff members of several day hospitals felt that their programs were not appropriate for elderly patients. They showed a lack of awareness that substantial numbers of elderly patients can benefit from programs designed to include them.

Outpatient care. Only one of the centers had a specialized staff to treat geriatric outpatients. Two had psychotherapy groups for the elderly, which were organized to meet the needs unique to their stage in the life cycle.

Two centers provided nurses who made frequent home visits to the elderly. Usually, an elderly person readily accepted a nurse's care because of her easily identified medical role. Sometimes only after establishing trust would the nurse tell the patient that she was from the mental health center. Another advantage of using nurses with elderly patients is that they are capable of responding to situations where both physical and emotional needs must be met.

Emergency services. Few elderly patients asked for emergency services, and no center had separate emergency facilities for them. A suicide prevention and crisis hotline in an area with a high suicide rate and high proportion of elderly was rarely used by old people.

One mental health center used the general hospital emergency room to receive psychiatric emergencies when the center's outpatient department was closed. The emergency service of a general hospital has the advantage of providing facilities for the physical diagnostic studies frequently needed by the elderly.

Consultation. The centers provided little consultation to the organizations that serve large numbers of the elderly, e.g., nursing homes, welfare departments, visiting nurses, "meals on wheels," and home health care programs.

Consultation to nursing homes was usually conducted on a case-by-case basis, although experienced consultants believe that greater long-range impact results from in-service education and policy-oriented consultation (2).

Nurses provided most of the consultation in nursing homes and were given considerable autonomy and responsibility in this area. They found such work rewarding, and their initiative built strong consultation programs. Backup by a psychiatrist who knew the nurse's capability was important, as when a nurse recommended a change in medication or hospitalization.

In one innovative program, the mental health center supervised staffs for 2 homes for the aged in conducting group therapy sessions for a large proportion of the residents.

Comment

The centers we studied devoted little effort to organizing prevention or treatment services based on an assessment of the greatest need for the population as a whole; rather, they focused on the elderly who came to them for help.

It is clear that elderly patients are not using inpatient, day-treatment, or outpatient services in proportion to their numbers. The site visits and a previous study (2) indicate several possible reasons for the low utilization rate.

1. *Lack of belief in appropriateness of mental health assistance.* The elderly are less likely than the young to believe that their problems are appropriate for mental health assistance. Normal elderly people outside the centers reacted to questions about mental health problems with anxiety, often expressed by nervous joking. Many thought that mental health services were only for "crazy people"; they associated mental prob-

lems with long hospitalization. Some described problems of depression, anxiety, and psychosomatic illnesses, but they had not considered it appropriate to take these problems to mental health professionals.

The majority of the centers were not devoting appreciable effort to educating the elderly about mental health. Many non-mental health care givers knew little about the services of the centers, and some believed that the centers did not wish to treat elderly patients.

One exception was a center that held public educational meetings at which topics relating to mental health and community organization were discussed. One of the purposes of these meetings was to increase community awareness of the individual's psychological needs. The sessions were highly regarded by other agency personnel. It seems likely that these efforts were successful because numerous care givers were remarkably alert to their clients' psychological needs and were familiar with the mental health services available.

Needed services can sometimes be provided without requiring elderly persons to accept the stigma of being mentally ill. Centers can cooperate with other organizations to provide mental health services as part of larger programs that carry no stigma. For example, two centers participated in the operation of multiagency sponsored groups that met away from the mental health centers and had goals that included socialization, education, and community organization as well as goals associated with traditional group psychotherapy. Another center participated in health screening clinics conducted by a health department for people over age 40.

2. *Transportation*. Problems in getting to a treatment center can be a serious obstacle for the elderly. Satellite facilities and home visits may help to overcome the transportation problem.

3. *Cost of service*. The ability of the elderly to meet the cost of mental health services is limited by low retirement income and the limitations of Medicare coverage.

One center that received little government financial support depended heavily on patient fees. As a result, it had a reputation among the elderly for being expensive. Another center, forced to reduce its day-treatment program because of reductions in Medicaid benefits, created several socialization groups in alliance with the local welfare department. The groups used a small paraprofessional staff. The change probably increased the overall effectiveness of the center because it served more elderly people and did not label them as mentally ill.

DISCUSSION

We believe that every mental health center should have a staff member designated as the advocate for the elderly. This advocate should be involved in policy making, clinical and organizational consultation to the center staff, in-service education, and community development.

We believe that services for the elderly should be integrated with the clinical services for other adults. Specialized services are likely to be inferior because the elderly are given low status in our society.

The future of population-oriented mental health services for the elderly is threatened. Increasingly, funds for health care come from third-party reimbursement, which requires a fee for service to a designated patient. Medicare is designed this way, and national health insurance, which is likely to be established in a few years, will probably follow the same plan.

How, then, are mental health centers to support population-oriented programs? NIMH funds, which in the past have supported some of these efforts, are being systematically reduced. Local and state funds could be used for these purposes when they are less needed to pay for direct patient services. However, after the establishment of national health insurance, community mental health centers are likely to be closely scrutinized about their need for continuing support from local and state governments. The centers will be required to convince such potential supporters that population-oriented services are valuable; yet most centers have not invested great resources or imagination in these programs, much less documented their effectiveness.

There is a grave danger that many centers may give up the struggle for population-oriented programs and choose the fee-for-service mode of providing care. This would be especially deleterious for the mental health care of the elderly.

Therapy Groups for Women

BY CAROL S. WOLMAN, M.D.

The author describes her experiences with two all-female psychotherapy groups, comparing these groups with both mixed-sex and consciousness-raising groups. Problems included a tendency of group members to drop out when dependency on the group became too intense and a lack of referrals to replace these dropouts, with resulting decreases in group size. The special strengths of such groups include the opportunity to concentrate on issues relevant to women, the possibility for development of a support system, the lack of sex-role divisions of labor, and the increased respect of members for other women and for themselves.

THIS PAPER describes my experiences with two outpatient psychotherapy groups for women only. Such groups are relatively rare in spite of the women's movement and have not received much attention in the psychiatric literature. They differ from both mixed-sex therapy groups and women's consciousness-raising (CR) groups and offer advantages over both for many women.

COMPARISON WITH MIXED THERAPY GROUPS

Since Broverman and associates documented the unconscious sexism of most therapists 5 years ago (1), very few consciousness-raising articles have appeared in the psychiatric literature. If what therapists read and write bears any relation to the way they practice, it seems that many therapists are still unaware of their own sexism. I define sexism as a belief system that includes the assumptions that 1) men are superior to women in various ways, 2) men should dominate women, and 3) women should be defined chiefly by their relationships with men.

A few therapists have written about sexism. Miller and Mothner (2) argued convincingly that women's oppression is real, and their striving for liberation is valid. They insist that the conflicts inherent in this striving should be examined in the therapeutic situation. Rice and Rice (3) also advocated active examination of the psychically crippling effects of sex-role conflicts in therapy, and called for more women therapists and use of the women's movement as a resource. Mintz (4) listed four sexist assumptions often made by therapists and therapy groups: 1) a woman who does not want to marry is abnormal, 2) a woman who does not want children is abnormal, 3) it is normal for a woman to lack ambition and 4) men should take the initiative in heterosexual courtship.

It is difficult enough to challenge sexist assumptions in an all-female setting; it is far harder in a mixed group, where the tendency of many women to seek approval and even self-definition from men is much more likely to be covertly reinforced than overtly challenged.

None of the classical literature on group therapy (5–7) even addresses the issue of the male-female power relations within therapy groups. There continue to be articles in which women are defined by their male connections (8, 9). Schonbar (10) and Fried (11) both discussed the power of a female therapist to act as a positive role model in mixed therapy groups, but they did not write about covert male dominance of women and how it could be handled.

A therapy group only for women eliminates most of the here-and-now sexism that goes on unconsciously in any mixed setting. It provides patients with the opportunity to explore the ways in which sexism affects their individual lives. Moreover, it conveys several covert messages that mixed groups do not convey: 1) women exist apart from men and are persons within themselves, 2) it is permissible and even desirable for women to bond strongly to each other and not to be chiefly defined by their bonds to men, 3) women are worthwhile and have valuable gifts to offer each other, and 4) men have no monopoly on power and goodness.

The patients in both groups I will describe were permitted, in fact encouraged, to become friends and to give each other support outside the group meetings. Therapists in most mixed-sex groups discourage outside contacts, their rationale being that such socializing would divert energy from the therapeutic endeavor. They may also fear sexual pairing. Mixed groups are usually expected to be time- and space-limited events where patients learn to change as individuals, transferring their growth to their home social situation.

My cotherapists and I had a somewhat different philosophy. Most of the women we saw were socially isolated and especially lacking in female friends. As Betty Friedan (12) explained, this restriction and isolation of

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Wolman is in private practice at 4348 26th St., San Francisco, Calif. 94131.

women is a post-World War II phenomenon. Smith-Rosenberg (13) documented the fact that nineteenth century American women maintained extensive female support systems. We believe that in addition to exploring their individual problems in a sympathetic group setting, women need to learn anew to depend on and value each other. Such interdependence eases problems of isolation and anomie and also teaches people to be dependable and to value themselves. We encouraged our patients to call each other for support between sessions, and at times helped to organize phone relays when a group member was in a crisis situation.

All-female groups obviously eliminate heterosexual interaction, and there was no homosexual bonding in our groups, although one patient was homosexual. It could be argued that these groups robbed patients of a chance to work through their oedipal conflicts. Like most people who seek psychiatric help, however, almost all of our patients had severe problems with basic trust and/or self-control and needed to concentrate on these problems. The absence of sexual attractions and games within the groups was a helpful simplification.

It might be feared that men would readily be scapegoated in all-female groups. This rarely happened. In fact, the patients tended to err on the side of self-blame, and the therapists often pointed out that a patient's grievance against a man might be legitimate and that she might have a right to be angry. For the most part, however, the patients concentrated on themselves and each other.

COMPARISON WITH CR GROUPS

These all-female therapy groups differ from CR groups (14–17), which form within the women's movement, in a number of important ways. The guding principle of most CR groups is that "the personal is political." As each woman shares her individual unhappiness, the group struggles to understand how her story illustrates sexism and to reduce her feeling of personal responsibility for her suffering. It is considered axiomatic that the problem is society-wide. Individual solutions are therefore impossible—women must fight sexism collectively. Paradoxically, many reports of CR groups (18–20) have emphasized the increased strength and personal mobilization that women gain from the CR experience.

The women who joined our therapy groups differed from women who seek CR groups in that they had defined themselves as psychiatric patients and were seeking professional help. They were referred to us by male therapists or male-dominated institutions and had not sought a women's group. They saw themselves as passive and helpless neurotic or dysfunctional individuals; they did not relate their problems primarily to their gender. Women who join CR groups may also be troubled, but they are seeking confirmation of the idea that at least some of their troubles are socially induced and occur because they are women. They have already opened themselves to the ideas of feminism and are functioning well enough to seek actively the specific type of group they desire.

CR groups are leaderless and opposed to expertise, although a woman with previous CR experience may help to get a new group going. No fee is involved, and the place, frequency, and duration of meetings are agreed on by the members. In contrast, the therapy groups I will describe had two leaders, both of whom had expertise as psychotherapists and as group facilitators. Patients paid $10 per session and met once a week for 90 minutes at a place chosen by the therapists. Structurally, these groups had more in common with mixed therapy groups than they did with CR groups.

DESCRIPTION OF THE GROUPS

The two groups developed quite similarly in some ways, and the differences between them were often instructive. H. Kathryn Ratner, M.S.W., and I worked with group A from November 1972 to June 1974. The group met as a service of the psychiatric outpatient clinic of a university hospital and residency training program. Most of the women in group A had never been hospitalized and received diagnoses of depression or psychoneurosis in their clinic intake interviews. Jeannette Black, R.N., and I ran group B as part of our private practices. We depended on both the community mental health system and on private psychiatrists for referrals. The group began in September 1973 and terminated in December 1974. All of the members had either been hospitalized or had spent several nights at a crisis unit. All had individual therapists. Their diagnoses ranged from schizophrenia to severe depression. (We excluded women who were actively hallucinating or delusional from group membership.)

In both settings we had trouble gathering enough referrals to begin the group and to replace patients who dropped out. This may be a general problem with group therapy. Our referral sources (most of whom were men) assured us that they thought a women's therapy group was a good idea, but we sometimes wondered if they had reservations they did not share with us.

Our intake procedure in both groups consisted of a 30-minute interview with each prospective patient in which both therapists asked her what she wanted from a women's group and what she needed to know about us in order to decide whether to make the required commitment to participate for 6 months. Since very few of these women had initially requested a women's group, they had no ready reply. Responses ranged from "I feel more comfortable with women than with men" to "I feel very uncomfortable with women, and I want to work on that." If a woman had no special desire to be in a women's group, we suggested that she

consider joining a mixed group instead. About 60% of the women we interviewed joined one of our groups.

Most of the prospective patients were quite taken aback by the thought of asking us questions about ourselves. They lacked the necessary assertiveness and saw us as authority figures whose credentials were not open to question. We found this part of the interview to be a good tool to demystify ourselves from the start and to make it clear that as consumers of mental health services, our patients had the right to "shop around."

The size of both groups fluctuated between 3 and 8 members. The patients ranged in age from 19 to 40. Most were single, divorced, or intermittently living with a man. Twelve women moved through group A and 8 through group B. The group A women were lower and middle class and most worked or went to school. All of the group B women were middle class and most did not work. None of the women in either group considered themselves feminists, although several had thought about the issues involved and were sympathetic toward them. In general, they complained of maternal deprivation and fear of their fathers. Three women in group A and 2 in group B had children.

Initial Phase

The initial phase of the groups was characterized by airing of problems, with frequent crises in group B. The women competed for the therapists' attention and help and offered each other little support. The desire to depend on the identified leader at first is strong in all groups, but it may have been heightened in our groups by the fact that the therapists were seen as maternal figures. The group members may have initially seen each other as deficient females.

It was remarkable how little overt talk there was about the lack of men in the group or about the special experience of being only with women. Instead, patients introduced male "ghosts," often talking about their husbands and lovers. As this was pointed out, they shifted the focus to themselves, their own strengths and weaknesses, and their bonds to each other. According to several observers, the initial phase seemed to be briefer for both these groups than for mixed groups.

Middle Phase

Both groups evolved into a well-functioning support system in the middle phase. This happened spontaneously in group A; it was actively encouraged in group B. The women carpooled to and from meetings, shared babysitting arrangements, and often had a meal together after the sessions. When a group member had a crisis, the others would support her with visits and phone calls during the week. There were parties and outings that the therapists did not attend. In group A, one member got a new job and bequeathed her old one to another member. In group B, one member was hesitant to return to school and the others escorted her to registration.

Group time was often used to explore problems in giving, receiving, and asking for help. Disagreements and conflicts among group members, as well as hard-to-express feelings of warmth and tenderness, were often worked through. The women learned to trust and care for each other and to respect their ability to offer friendship.

During this middle phase, group members tended to see one of the therapists as "male"—cold, nongiving, authoritarian, and punitive—and the other as "female"—warm, nurturing, available, and forgiving. Usually, I received the "father" transference, probably because I have an M.D., a higher status degree than an M.S.W. or an R.N. My personal style was also more nondirective that either of my cotherapists'. Thus the patients tended to divide their transference according to prevailing male and female stereotypes, despite the reality of an all-female group.

Several members reported that the men close to them (including some male therapists) seemed to feel threatened by their participation in an all-female group and even made it difficult for them to attend meetings. These women seemed to be feeling a conflict between their role as wife or girlfriend and their wish to be more self-assertive, with the group representing the latter possibility.

The members became extremely dependent on the group. They often said it was the most important event of their week, and many made financial sacrifices to attend. It would be inaccurate to say that these were entirely transference feelings, since the group was in reality fulfilling some of the members' needs. Of course, it could not fulfill all of their needs, and several members of both groups manifested extreme rage and disappointment at times. The rage tended to focus on the therapists, who had a policy of not offering support outside of the meetings. In group A, 2 of the women were used to expressing anger and taught this skill to the others. In group B, rage was an unaccustomed and explosive phenomenon. Some of the women in both groups were able to work through their rage successfully and move on to new levels of autonomy. In each group there were 2 or 3 members who ventilated their rage and then fled the group. In some cases, women developed a sudden new dependence on a man when they were too frightened by dependence on the group. Unfortunately, the women in group B were unable to cope with the frequent losses and the group eventually terminated because of attrition.

This middle phase was thus notable for dropouts, for active transference, and for increasing intimacy among the women who remained. The frequent losses gave the remaining group members an opportunity to practice mourning and to learn the realistic limits of their responsibility to other people.

Final Phase

In the late or "ripe" phase both groups were quite small (3 to 5 members). They dealt extensively with being female, covering such issues as sexuality, mothering, sexism, and dating patterns. Most of them

showed increased self-esteem, and several began planning new occupational or educational endeavors. Some of their ambivalent bonds with men dissolved; others matured and deepened. They discovered that masturbation was helpful, and several became orgasmic for the first time. The women with children seemed more at ease with mothering and reported improved relations with their children.

In group A, the remaining women thought of each other as sisters. In group B, where flight overwhelmed intimacy, the 3 members who remained were not very close outside the group. In both groups, however, the therapists were demystified by this time. We were no longer seen as omnipotent and as withholding love but rather as professional women with interesting lives who could serve as role models in some ways. The patients also began to see their own parents more realistically and to be less afraid of their fathers.

Group A terminated when I moved to another city 2 years ago. The members have kept in touch with each other and with me since then and have helped each other through hard times, even though they now live hundreds of miles apart. One of them died of leukemia; the others visited her frequently and gave her husband support after the funeral. The members of group B have not kept in touch with me.

DISCUSSION

The groups I have described were similar in many ways to mixed therapy groups. The patients worked on the same types of issues that patients in mixed groups work on, and the therapists used the same skills and techniques that other group therapists use. However, these two groups had certain inherent problems that mixed groups do not have. First, there was no heterosexual bonding to hold members in the group when they wanted to flee. I can only surmise from the tendency of group members to find a new boyfriend when they quit the group that the presence of men might have prevented some dropouts. Second, the overwhelming dependence on the group that most of the patients developed might have been intensified by the equation our culture makes between "female" and "nurturing," as well as by the therapists' policy of fostering a support system. In mixed groups, dependency may be mitigated by the need to maintain sexual distance among the members.

Women's therapy groups also have special strengths to recommend them. There is less covert sexism and it can be more easily confronted, and the group can concentrate on issues relevant to women, particularly sexism. In group B, the therapists shared their perceptions of sexism, and gave advice on how to fight it. Such intrapsychic wounds of sexism as fear of assertiveness, the tendency to define oneself as wife, mother, girlfriend, or sex object rather than as a person, masochism and deference to men, hatred of other women and concomitant self-hatred, and repression of one's ability to think can be put in context, shared in the group, and healed. Group members feel safer and more comfortable than they would in mixed groups. Because they tend to let themselves depend so heavily on the group, they have the opportunity to work through issues of rage about not receiving enough nurturance and to learn true autonomy in this setting. The women experience women leaders functioning in authority roles, which teaches them that women can have power and deserve respect and provides them with role models. There are no sex-role divisions of labor, despite the tendency of the members to perceive such divisions. Both therapists are women, and both carry out nurturing and reality-testing functions, teaching that women are strong and complete. There is also much less need for inhibitory incest taboos. True intimacy among group members can develop more readily than in a mixed group, and there is less need for prohibitions on outside contact; thus a true support system can form. Such a support system is extremely valuable to its members, whose lives are often anomic and lonely. Moreover, the bonds among members can be scrutinized clinically in the group meetings, and the therapists can help the patients learn better skills of sharing and caring.

All-female therapy groups can be very helpful to women who seek psychiatric assistance. They do many of the things that consciousness-raising groups do, teaching women to respect other women and themselves, and providing an opportunity to identify common problems. At the same time, women in therapy groups can avail themselves of the skilled help of professional therapists.

Journal Policy on Multiple Authorship

It has come to our attention that there has been some misunderstanding regarding the *Journal*'s policy on polyauthorship. The number of authors listed on a paper is not a factor in the review and acceptance/rejection procedure. However, once a decision has been made to publish a paper, we do apply *Journal* policy regarding the number of authors in the by-line: only principal researchers and writers of articles are listed in the by-line; collaborators who have provided technical and other assistance are acknowledged in a footnote. In papers that list more than 4 people as principal authors, we query the first author to verify that those individuals were substantial contributors to the research or ideas reported. Since certain types of psychiatric research may require multiple workers, we will of course include all of the names in these cases.

Experiences of Psychiatry Board Exam Casualties: A Survey Report

BY MARTIN R. LIPP, M.D.

The author collected completed questionnaires from 52 psychiatrists who had failed to pass the examinations of the American Board of Psychiatry and Neurology (ABPN) on their first try. He quotes from the responses of 6 of these psychiatrists, showing the profound emotional impact of their failure. He recommends that the ABPN explain its low pass rate, supply feedback on the exam results, provide the specific criteria by which competence is judged, allow candidates to take the written exam on a trial basis, and drop the oral exams if their reliability cannot be documented. He also recommends that the profession of psychiatry take responsibility for the certification procedure.

FOR THOSE WHO PASS the American Board of Psychiatry and Neurology (ABPN) examinations on their first try, certification is probably not a major event in life. The certificate gets framed and hung on the wall or placed in a file or safety deposit box with the dozens of other pieces of paper that chronicle our lives and our professional achievements. The ordeal of studying gradually fades and may even assume a certain luster in our memories along with other battles well fought.

However, for those who do not pass the examinations on the first attempt (or, for some, ever), the experience assumes very different proportions. The intent of this paper is to record and discuss the subjective experiences of colleagues who have become "Board exam casualties."

The statements cited here have been extracted from the returned questionnaires of psychiatrists answering advertisements in *Psychiatric News* and the *Northern California Psychiatric Society Newsletter*, as well as those of colleagues contacted personally and those who responded at the 1975 annual meeting of APA. The questionnaire asked the respondent to detail his or her subjective experiences as a Board exam casualty. A total of 52 completed questionnaires was collected.

I make no pretense that this sample is representative of the entire population of Board exam casualties or that the results are in any way statistically significant. This report's value depends on the heuristic impact of fragments of personal testimony on readers who have shared or will share the Board exam experience—and on our profession as a whole.

The 52 respondents ranged in age from 32 to 65; they had completed their residencies in years ranging from 1950 to 1975. All but 4 of the 52 respondents stated that English was their native language. Their experiences with the exam varied—from some who had taken their written exams once, failed them, and decided not to try again, to 1 psychiatrist who took various parts of the exam six times before completing the whole exam successfully. Twenty-three of the 52 respondents were certified by the ABPN at the time these data were gathered.

The following quotations from the answers of 6 of the respondents were chosen to illustrate the range of subjective experiences and because these respondents related their perspectives in a particularly articulate fashion. The remarks are essentially verbatim, although abbreviated, with stylistic changes for readability.

QUOTATIONS FROM RESPONSES

Colleague 1 (Age 35)

The exams were a significant professional landmark for me because I could not remain on the faculty of the university where I teach without Board exams and would not be able to assume the administrative position which I sought. I studied an average of six hours per week for six months preceding the written exams, as well as studying for about ten days prior to the writtens. For the oral exams [1974], I put myself through a series of mock oral examinations in both psychiatry and neurology.

When I learned I had conditioned psychiatry, I responded with shock, panic, severe embarrassment—wanted to get away—called a friend of many years and spent an hour talking with him in the park. Was quite depressed, felt stupid, worthless, a failure, fell asleep obsessing over each examination, wondering what I did wrong, woke up early in the morning thinking of the exam. No therapy—wished afterwards I had. Had a hiatus in work and writing, seemed to mark time, drain on all my energies, withdrew from colleagues, and

Revised version of a paper presented at a forum at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

At the time this paper was written, Dr. Lipp was Chief, Psychiatry Consultation Service, San Francisco Veterans Administration Hospital, Calif. He is now with the Permanente Medical Group at Kaiser Hospital, Hayward, Calif., and in private practice in San Francisco, Calif. Address reprint requests to him at P.O. Box 26393, San Francisco, Calif. 94126.

avoided teaching activities. More irritable with family, lost sense of humor. Did not want to be in social setting with colleagues. Considered leaving psychiatry and taking up general practice or neurology and just getting away.

This was my first real failure, and I felt helpless as a consequence. The experience of failure was lonely and isolating. Able to tell only three colleagues and my wife. Responded to the experience by requesting information from the Board and received a nonspecific reply which was not helpful. Felt at a loss to know what the next examiner would want, complained about the subjectivity of the experience, and was bitter because the comments returned by the ABPN in no way reflected three years of evaluation by supervisors in residency training. Ultimately I retook the oral exam in 1975 successfully and am now a Board-certified psychiatrist.

Colleague 2 (Age 41)

I put a great deal of time, money, effort, and ego into the taking of my exams. When I learned that I conditioned my psychiatry orals [1972], I was shocked and stunned. Not clinically depressed or suicidal. It was my first such failure. I felt it was a fluke, something completely out of line and inappropriate, as much the ABPN's fault as mine. No effect upon my work, social life, family life, except for the necessity to do more studying. My only previous failure had been a divorce with which I coped by going into a seven-and-a-half-month-long clinical depression, which required therapy. Failing Boards scores 10 on a scale of 100. The divorce scores 90.

Another response to my failure was to write the Board. The ABPN was very gracious in indicating to me the sources of my poor showing. This was the key, incidentally, to my passing the next time around. My exam performances both times were at a lower level than my usual performance. Certification is like a Phi Beta Kappa key, not everyone who has one *really* deserves it. Many who do not have one are of equal or higher caliber than those who do. Yet the Board certification has opened doors to me otherwise unavailable.

Colleague 3 (Age 53)

I put a great deal into Boards. Studied 20 hours per week for one year. Took a mail-order course, went through a neurology review book, and so forth. Forsook nearly all social and family life; the experience prolonged my training analysis about one year. Upon receiving notification of failure [1971], was disappointed, very angry, and bitter. Mildly and transiently depressed, but my training analyst helped me work that through.

There was little effect on my private practice, but I lost about $280 per month at my part-time government job. At times, when put on the spot, I feel like a second-class citizen: the well-trained child psychiatrist I am, forever excluded from certification in my field because of my lack of certification in the adult Boards. Apologetic explanations are often necessary for why I am not Board certified.

I never really failed at anything important in the past. In this case, at my age, I was not willing to try again—wouldn't know where to start. A number of questions are unanswered. Did I fail by a little or a lot? Where was I weak, neurology or psychiatry? Did *I* goof or was the test unfair? I did not get any feedback about these questions.

I've been able to talk about my experience with only a very few select colleagues. Although I do not believe my performance on the exam was representative of my performance generally, I blame myself to a large degree. I am not really sharp on that type of test. My clinical style is more slow and deliberate. In some ways I believe I have *too much* knowledge, and I am aware of too many "ifs" to do well on a multiple-choice exam. In that sense the ABPN is very much at fault.

There is one additional factor you should know about. During my prolonged studying for the exams and the prolonged emotional tension associated with it, I neglected many physical symptoms because I regarded them as part of the stress I was under. Because of that neglect and the additive effect of stress, I ended up requiring major abdominal surgery. I have no intention of ever subjecting myself to that ordeal again.

Colleague 4 (Age 43)

In my entire life this was my only failure, although in the long run I may be a better person for it. I put a great deal of ego involvement, time, and effort into studying and taking the exams [1962]. Afterwards, I was mostly very angry, with intermittent feelings of depression and shame. I had thought that I did well in neurology and psychiatry. After being informed that I failed both parts of the exam, I was shocked. I contacted my examiners in neurology personally, all of whom told me that I had done satisfactorily and that they had passed me. My attempts to find out how I could have failed both parts were in vain. I could never find out why I failed. My best *guess* is that somehow I rubbed one of the psychiatric examiners wrong—so badly that I was therefore flunked on everything.

At the time I took the exam, I felt that my level of training and my skills were excellent. I had gotten recognition as an excellent resident at my highly regarded residency, been director of a military mental hygiene clinic, written several clinical papers, taught psychiatry to medical students, and been a successful clinician in private practice. Since failing the Boards, I've gone on to graduate from a nearby psychoanalytic institute, been actively involved in training at a prestigious local neuropsychiatric institute, been consultant to many agencies, presented papers at various APA meetings, and so forth. We seem to be entering an era of medicine where it would be "good" to have one's Boards. I would even be willing to restudy the psychiatric part, but it's just too huge and unpleasant an undertaking to have to restudy neurology.

Colleague 5 (Age 65)

I put a considerable amount of energy into preparing for the Boards [1959], and I did not expect any particular trouble in passing. Afterwards, I felt disappointed and disillusioned. I got the feeling that the Board was not interested in helping me pass. My residency training, all in the military, did not stress or prepare me for Boards. I felt that a good overall knowledge of psychiatry would be sufficient, but it proved not to be. I had had other experiences with failure in the past and believe them to be my fault; in this instance, I feel the Board itself was unfair.

What little feedback I did get was essentially that I was military trained, that "the Board had to" fail its quota, and that people like me had to expect to fail at least for a time or two. On both occasions when I took the exams, first in New Orleans and then again in Chicago, I felt the examiners (mostly quite young) were openly antimilitary, and I was a captain on active duty when I took the Boards. I have been a physician for 38 years and in psychiatry since 1949. I have been chief

of psychiatry in three hospitals and chief psychiatrist at a state prison. I believe that my experience and accomplishments deserve some recognition from my profession. I have been a member of the APA since 1951, and as far as I can see, among "the brethren" I am a nobody.

Colleague 6 (Age-51)

In studying for the orals, I spent six months of daily intensive study, as well as one month of full-time six-hours-per-day studying. Much ego involvement, family interest, and investment of money. When I heard of my "failure," I responded with surprise, disbelief, anger, frustration, indignation. The exam has had no effect on my practice; I was appointed superintendent of a large state psychiatric hospital after taking and failing my first oral exams. My family was disappointed. Colleagues were supportive.

The problem with Board examinations lies in examiners' not attempting to test you on *what you know* but on what they know best and their structuring the exam on a professor-student level rather than as colleagues. The ABPN is too rigid and is controlled by men who are too far removed from real psychiatry to know the difference.

In October 1974, test conditions were awful in New York, crowded and hurried, with many long journeys across town by taxi. Although I am a superintendent of a state hospital, I was given two adolescents during the psychiatry hours and never asked about administration, forensic psychiatry (which I know well), or community psychiatry. One patient was a 15-year-old girl with anorexia nervosa, and the examiner was a chairman and professor of child psychiatry; she was the first such case I had seen in 21 years of medicine. You can imagine the odds. When we finished, he said, "You certainly did a marvelous interview and handled the patient well"—and then he failed me.

On reexamination, I passed psychiatry and conditioned neurology, therefore failing the exam as a whole. The neurology examiner was culturally and socially not atuned to me, and he dominated the other examiner, who seemed more on my wavelength. It was extremely hard for me to appear to be a junior medical student when I have been a person in authority for so long, although I tried my best after New York. Although I frequently read EEGs, the neurologist marked me up for not knowing EEGs, which I do not remember a question about.

DISCUSSION

This discussion will be brief so as not to detract from the impact of the first-person narratives and because it is hard to know what to say that has not been articulately and sometimes poignantly illustrated above. However, I will try to emphasize some of the more widely held or recurring themes.

First, it is apparent that being a Board exam casualty has a profound emotional impact on those who share the experience. All of the respondents experienced depression, some of considerable magnitude, although none reported suicidal ideation or abuse of alcohol or drugs. Overwhelmingly it was a lonely experience, to be shared openly with very few others. For many, shame, bitterness, anger, bewilderment, helplessness, and frustration were important themes that dominated their lives for months or years after learning their exam results. The personal and professional cost of these often painful emotional states is impossible to assess, but it would be fatuous to assume that the cost is negligible. Several casualties blamed their Board experience for major repercussions in their private life. Although the merits of any given case are certainly debatable, the painfulness of the experience for many can hardly be argued.

Second, the absence of spontaneously given feedback was a source of frustration for practically all of the respondents. The recently developed Board policy of giving feedback on oral exams for those who request it was clearly regarded as a positive step, although many of the respondents took issue with the specifics of the criticism rendered. Others were aggrieved that the availability of feedback was officially a secret and not mentioned explicitly in the ABPN brochures. To deprive a duly trained and experienced psychiatrist of confirmation of his or her professional identity without saying why seems unfair. No other single aspect of the examination procedure was the source of so much resentment.

Third, there was widespread criticism of logistic hurdles encountered in the exams. These both increased the cost of the experience for the candidate and at the same time made it more traumatic. Again, it is impossible to say whether the stories told by the respondents are apocryphal, whether these problems contributed to the casualties' exam performances, or even whether logistical problems occur more frequently with casualties than with noncasualties. However, anecdotes abound: candidates in one location told of having an unexplained 70-minute delay before beginning the written exam in 1972; exam sites and schedules were changed at the last minute one year; a proctor in a written exam gave a running discourse about local restaurants in 1975; one year a candidate from Philadelphia was assigned to take written exams in Washington, D.C., at the same time that a colleague from Washington journeyed to Philadelphia to take the exam; both candidates and examiners were flown from the same California city to go through the oral exam ritual together in New York City in 1974.

Fourth, a concern relating to the ambiguity of the criteria by which a candidate's performance is judged was often noted. The weight of this criticism fell on the oral exam, but the written exams were not immune. One example in a written exam was a question that could be answered one way if the respondent used Bleuler's criteria for schizophrenia but another way if Schneiderian criteria were used. The respondent who told about this question decided that the more widely used Bleulerian criteria were probably called for, but he felt that this question was typical of an exam that sought simple answers, penalized sophistication of knowledge, and lacked clarity concerning which authorities were being used as a standard for what is "correct."

The comments were particularly biting on the topic

of the oral exams, in which subjectivity clearly can play a larger role. Candidates frequently complained of being judged according to an unknown yardstick by examiners whose unknown biases, theoretical preferences, and emotional states dominated the exam's results at the expense of any objective assessment of candidates' expertise in representative clinical settings. Reference was often made to the American Board of Internal Medicine, which abandoned oral exams after finding that exam scores correlated more with the identity of the examiner than with the identity of the candidate. One respondent commented, "At a time [1973] when the American Psychiatric Association had just formed the Task Force To Define Mental Illness and What Is a Psychiatrist, it seemed ludicrous to ask candidates to answer oral exam questions in the absence of explicitly stated criteria on which we will be judged."

Fifth, a number of older practitioners argued persuasively and poignantly that the examination procedure discriminates against psychiatrists who have been out of school for many years. Taking multiple-choice exams, they pointed out, is an acquired skill that they never had an opportunity to develop because it was not in vogue when they were in training. Even if they had had such experience, it was so far in the past that their talents in taking this kind of exam had long since atrophied. The oral exams are also more difficult for older practitioners, both because they have had less recent experience with question-and-answer repartee and because being scrutinized by young examiners with a fourth of their clinical experience has its humiliating aspects.

Sixth, many casualties believed that the responsibility for their failures remained an unresolved issue. Some blamed themselves, others blamed their residencies, many blamed the ABPN. Most of the respondents implicated more than one factor. No one specifically blamed the profession of psychiatry or the quality of psychiatric knowledge per se, although many felt that they had been unfairly penalized by the absence of agreed upon, reliable criteria for judging professional competence. Several felt that residency training programs should share the pain when their graduates do poorly on a Board exam. Although the thinking here was not clearly stated, two factors seem to be involved: 1) to punish and restrict programs that consistently fail to assist their graduates in the process of certification and 2) to give the residencies a greater impetus to confront and help modify a Board that is generally seen as unresponsive to input by individuals.

A final issue relates to the reluctance of the respondents to undergo the same ordeal again. Even those who were preparing for a repeat examination clearly were doing so with reluctance and even dread. With the prospect that mandatory recertification is becoming an increasingly likely reality, a number of respondents voiced the hope that recertification will be applied equally to all. One respondent stated, "Who will examine the examiners? If they have to go through the same procedure as I do on a regular basis, at least that will tend to reduce the arrogance and insensitivity which I personally encountered. No grandfather clauses, please!" In the absence of such safeguards, recertification procedures will be met with profound cynicism, as a rote performance demanded by the haves for the purpose of excluding the have-nots.

RECOMMENDATIONS

The suffering inherent in our current system of Board examination demands that something be done. Almost two-thirds of all psychiatrists (our noncertified brethren) are disenfranchised by current practices. I am embarrassed and ashamed that I can advance the following suggestions only now that I have successfully completed this official rite of passage:

1. The ABPN must be held accountable for the extraordinarily low rate of passes that characterizes its procedures. The pass rate for psychiatrists on part I of the exam (the written portion) was 63% in April 1974. Recent pass rates for graduates of U.S. medical schools for part II (the oral portion) ranged from 58.4% (Los Angeles, April 1974) to 68.7% (Atlanta, February 1975), resulting in a successful completion rate for both parts of the exam ranging from 36.8% to 43.3% (1). Because these figures place our certification procedures at the most stringent extreme of all specialty boards (2), the ABPN must be asked to explain and justify their punitive and arbitrary standards.

2. Feedback must be included as an integral part of the examination procedure. All candidates, successful or not, should be told as a matter of course where their perceived strengths and weaknesses lie. Further, this information should automatically be transmitted to each candidate's residency training program. In addition, success-failure ratios for all residency programs should be published in the *American Journal of Psychiatry* along with the published names of successful candidates.

3. The ABPN must provide specific criteria to the candidates, advising them precisely by what standards they will be judged. If specific, measurable criteria and scales of professional competency exist, there is no reason for keeping them a secret. If they do not exist, we must recognize the caprice and subjective bias with which professional competence can currently be determined and therefore grant certification automatically to anyone who completes an approved residency.

4. All candidates should be allowed to take the written exams on a trial basis without penalty and without exhorbitant cost. This certainly should be the case for older candidates who have only remote experience with multiple-choice exams; in fairness, however, everyone should have this opportunity.

5. Unless the oral exams can clearly be demonstrated to be free of the subjective bias with which they are so frequently charged, they should be dropped from the examination format. At present, a

good case can be made that the oral exams provide only a facade of examining clinical competence.

6. Our profession as a whole must take responsibility for the certification procedure that helps to define us all. Although scapegoating the ABPN often seems an attractive alternative, it is sheer sophistry to do so. The task belongs to all of us. Is not the practice of psychiatry difficult enough without adding this additional burden to the role we have chosen for ourselves? In short, what are we doing to ourselves and to one another?

Change in 1976 Annual Meeting Site

The APA Executive Committee decided to move the May 10-14, 1976 APA Annual Meeting from Atlantic City to Miami, Florida, after hearing the APA Meetings Management Department report that it had ascertained that a major Atlantic City hotel had inadvertently committed several hundred rooms to another organization during the week the APA meeting was scheduled. This would have left APA with the unacceptable alternative of using a myriad of scattered small hotels in the Atlantic City area. It has been confirmed that Miami Beach can accommodate the meeting.

Further arrangements and developments will be reported in future issues of *Psychiatric News*.

Effect of Drug Ritual Changes on Schizophrenic Patients

BY RODNEY W. BURGOYNE, M.D.

The author evaluated the charts of 115 chronic schizophrenic patients who regularly attended a follow-up group to determine whether changes in long-standing medication regimens produced an increased dropout rate, decreased attendance, or psychotic decompensation. He found that although there were nonsignificant trends showing a relationship between medication change and group attendance for individual patients, there were no significant differences between group attendance and change or no change in medication routine for the group of patients as a whole. He concludes that necessary changes in medication routines for chronic schizophrenic patients are safe.

THIS PAPER REPORTS the effect on outpatient attendance of changing the drug routines of stabilized chronic schizophrenic patients. In contrast to studies that have assessed the effect of antipsychotic medication, this study measures the effect of factors surrounding the use of maintenance drugs per se. It was designed to determine whether changes in long-standing medication regimens produce an increased dropout rate, decreased attendance, or psychotic decompensation in previously well-stabilized patients who were regular attenders of follow-up groups.

BACKGROUND

The establishment of community mental health centers in the 1960s promoted the use of maintenance antipsychotic medication, the less routine use of long-term hospitalization, and an increased interest in post-hospitalization outpatient aftercare for schizophrenic patients. Outpatient psychotherapy was first modeled on modifications of psychoanalytic concepts. Special "Tuesday afternoon groups" (1) or "Wednesday afternoon clinics" (2) denoted that a nonintrusive, supportive, nonthreatening form of psychotherapy should be used. Research studies noted that group therapy was more effective than individual therapy (3, 4) and that aftercare coupled with short hospitalization (5) or day care (6) was as good as or better than prolonged hospitalization.

Although some think that an adequate assessment of the effect of using or discontinuing antipsychotic drugs, particularly when they are given in low doses, has not yet been made (7, 8), there is general consensus that maintenance antipsychotic medication is useful in the treatment of many, if not most, schizophrenic patients.

Similarly, although a proper assessment of the effect of psychotherapy on schizophrenic patients has yet to be made (9), it remains an almost ubiquitous clinical impression that the resocializing, supportive "active" psychotherapies are helpful. Many different psychotherapy techniques are used with schizophrenic patients; there is little agreement on which is most helpful or why it may be so. Therapeutic interventions may hinder the recovery of some patients or even drive them away from treatment. Sometimes patients are considered improved after moving from one setting to another (10). Simply talking with patients about their behavior since they were last seen correlates with a decrease in rehospitalization rates (11). Perhaps aftercare groups are effective because they provide modeling of how others have coped with their problems (12). The effect of any given approach on chronic schizophrenic patients as a group remains questionable.

In spite of the importance of social and supportive therapy for these patients, the major initial factor in successful treatment is antipsychotic medication. Patients who do not come for outpatient aftercare may discontinue their medication. They are also deprived of social therapy at a time when it has been demonstrated to do the most good—after 18 months (13–15). In an effort to prevent unnecessary stress, it is widespread practice for therapists to allow questionable drug regimens to continue unaltered for months, thereby avoiding conflict with patients over their medication.

The Follow-Up Clinic

At the Los Angeles County-University of Southern California (LAC-USC) Medical Center, years of experience with large numbers of patients who require continuing care have resulted in a program similar to that recently described by Isenberg and associates (16). At the LAC-USC Center, psychotropic medication is considered primary, but social and supportive psychotherapy is stressed.

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Burgoyne is Assistant Professor of Psychiatry, University of Southern California School of Medicine, and Associate Director, Adult Psychiatric Outpatient Clinic, Los Angeles County-University of Southern California Medical Center, 1237 North Mission Rd., Los Angeles, Calif. 90033.

Twenty groups meet for 45 minutes once a week. Five groups meet at one time in the follow-up clinic. Each group may have 40 to 60 patients enrolled as members, but the weekly attendance averages about 18 patients. Some patients come each week, others every other week, and some less often. Many of the patients in these groups have been attending for years. For some of them the clinic has become a family substitute, and the patients have formed an allegiance to the institution rather than to specific doctors. Before the group meets, many of the patients gain gratifying input through socialization over coffee in the large waiting area (17). Afterwards, medications are refilled for each patient individually.

Because it is less effective for chronic schizophrenic patients (18), individual therapy is discouraged, but it is used when necessary to interrupt a crisis. Movement therapy (19–21), vocational rehabilitation (22), and help with social welfare agencies are readily available to appropriately selected patients (23). Most group therapy work is done through metaphor and latent language communication (24). Restrictive solutions (25) to group conflicts are used more often than other solutions. Interaction is almost always supportive and goal directed and only occasionally intrusive (26). To avoid augmenting any disappointment the patients may have encountered with outside-world relationships, interaction within the group is kept empathetic but firmly reality oriented (27).

One early goal of the follow-up clinic is to enable the patient to recognize his narcissistic and anaclitic needs (28) and to focus on abilities that are either already in the patient's behavioral repertoire or that can be developed to appropriately meet these needs. The difficulty this task imposes on the usual schizophrenic patient is recognized and stressed (29), but hope is fostered and successes are actively acknowledged (30). Severe symptoms, such as hallucinations, are interpreted as evidence of the need for medication and as a communication of the patient's dependency needs, but they are not solicitously emphasized (31).

Remaining out of the hospital is recognized as a significant success. As others have also noted (14, 32), there are surprisingly few patients participating in these groups who are hospitalized.

A few patients come to the clinic only for medication and do not attend the group session. These patients give various excuses, but apparently they do not attend because either they are more paranoid and isolated or they are not limited in social contacts and feel they do not need the group (33).

When therapist replacements are necessary, they are made relatively smoothly and are structured to facilitate allegiance to the group and to the institution as a whole rather than to the therapist.

Clinical Observations on Attendance

When a therapist of one of these groups becomes ambitious and presses for introspection or acknowledgment of feelings or sets higher goals for social and productive functioning, the anxiety level of the group rises and attendance dwindles. Anxiety is seldom acknowledged by the patients as a reason for poor attendance. This is usual for schizophrenic patients, who have great anxiety and have to withdraw from the activities of life to keep it under control while presenting a blunted exterior to the world (34).

Changing drug routines appears to place significant stress on these patients. Sometimes they are not allowed to maintain the social safety they need by isolating themselves when interaction becomes focused on a change in their long untouched medications. This change requires increased monitoring and attention. Other times this change may provoke open disagreement. Patients who have maintained the same medication pattern for years and have not suffered acute exacerbation of their psychoses are particularly likely to resist any change.

The risk of tardive dyskinesia and other side effects of long-term antipsychotic maintenance drugs necessitates periodic medication review, drug holidays, and lowered doses. Therapist anxiety sometimes leads to unnecessarily extreme or poorly timed medication manipulations. This is particularly true if a patient has been on a mixture of several drugs. Occasionally the former drug routine is denigrated when changes are administered, thus undermining the patient's trust in the clinic and in his doctors. Because the expectation of help and a feeling of success in gaining it are necessary for treatment to continue (30), poor attendance after a change in medication seems understandable.

Many patients strongly believe that their medication regimen keeps them compensated. Evidence supports their belief that they tolerate more stress when receiving antipsychotic medication (35), although at times their allegiance to the drugs appears magical. Unfortunately, these patients may appear merely overly dependent on their medication, a view that allows the doctor to abruptly change the prescription. Patients who challenge such changes by an insecure doctor sometimes cause him to defensively assert his will and further undermine rapport.

Because of the long washout period of most antipsychotic drugs, even discontinuance produces little pharmacological effect for a while. In properly medicated, stabilized patients, changes in routine have significant effects (36). It is often assumed that major medication manipulations will therefore produce significant unwanted stress, possibly leading to diminished or ceased attendance at aftercare programs altogether.

METHOD

Patient Selection

Patients included in this study had a firm diagnosis of schizophrenia, had shown regular (twice a month or more) attendance at a follow-up group for the six months preceding the study, were receiving major antipsychotic drugs, and had been receiving a stable and

unchanged dose for four months before the study.

In an effort to refine the diagnosis of schizophrenia, the clinic therapists made a judgment based on several months of experience with the patient as to the presence of first-rank Schneiderian symptoms (37). Patients who did not currently exhibit these symptoms were diagnosed as schizophrenic if they had recently exhibited them and if they had a history indicative of chronic schizophrenia. Of over 600 patients who attended the follow-up clinic, 115 met these criteria and attended the clinic during the five-month study period.

Of the 115 patients, 59 were men and 56 were women. Their ages ranged between 19 and 62. Their median age was 38, and most of the patients fell into the 28–52-year-old range. Sixty-one patients (53%) were white, 35 (30%) were black, and 19 (17%) were Mexican-American. Fifty-eight were married or lived with someone considered to be supportive, and 57 claimed to live totally alone.

Measurement of Variables

Patient attendance over the five study months was divided into those whose attendance was unaltered (continued two times or more a month), was diminished but regular (averaged at least one time a month), was interrupted (for at least one month), or ceased.

The medication regimen changes that occurred during the five study months were deemed necessary in the clinical judgment of therapists blind to the study. The medication regimens are divided into the categories of no change, minor change, and major change. A major change was defined as a substantial change in dose of a major antipsychotic drug and/or of any concomitantly given tricyclic antidepressant. A minor change was defined as any other medication change. More specific criteria are as follows:

Major medication change criteria. 1) Substantial increase or decrease of dose of an antipsychotic drug (plus or minus 5 mg of trifluoperazine or thiothixene or plus or minus 50 mg of chlorpromazine, thioridazine, or their equivalent); 2) addition to, discontinuance of, or substantial change in dose of concomitantly given tricyclic antidepressant (50 mg of imipramine or its equivalent).

Minor medication change criteria. 1) Addition to, discontinuance of, or change in dose of hypnotics, antiparkinsonian drugs, or benzodiazepine drugs; 2) changes in antipsychotic drugs within the same group to another of approximately the same potency dose or involving time of day or division of dose; 3) any other medication addition or change deemed of possible importance in my judgment. (I reviewed the changes because I had not been the therapist for any of these patients.)

RESULTS

The charts of the 115 patients were reviewed for five months. The attendance patterns were unchanged in 61 patients (53%), regular but diminished in 23 patients (20%), interrupted for one month or more in 26 patients (23%), and totally discontinued (not seen at all in the last two months of the study period) in 5 patients (4%).

Sixty-one of the patients (53%) had no medication changes during the study period. Seventeen patients (15%) had minor changes in medication, and 37 (32%)

Mexican-American (N=19)	7	5	7

* There was a significant difference between the white patients and the other patients in attendance patterns ($\chi^2=6.365$, $p<.05$).

had major changes. Of the 54 patients whose medication was changed, two-thirds had a major change according to the study criteria.

No significant differences were found between attendance patterns and changes in medication (see table 1). There were nonsignificant trends suggesting that a change in a long-established medication regimen might be related to attendance in some specific patients, but these trends were not significant for the groups as a whole (see table 2). No matter what comparison was made, attendance and medication change were independent of one another. There was no evidence that medication regimen manipulation has, on the average, any significant effect on the follow-up clinic attendance of stabilized chronic schizophrenic patients.

Table 2 lists some other variables thought to possibly relate to attendance patterns. Analysis revealed no significant differences between gender, living alone, or dose level of antipsychotic medication and attendance patterns.

When only the extreme groups (no change in attendance and interrupted or ceased attendance) were compared with age (above the median and below the median age), there was a strong trend for younger patients to change attendance more often, but the difference was not statistically significant ($\chi^2=3.374$, $p<.10$). Clinical experience confirms that younger patients have more difficulty identifying themselves as members of groups of chronic mental patients. Perhaps that is fortunate for them.

Patients of minority ethnic groups changed attendance patterns significantly more often than white patients (see table 2). This has been observed at our clinic and elsewhere (38, 39). One of the causes of this difference in attendance patterns of minority patients might be their feeling that they do not belong. One hopes this will change as the number of therapists from minority groups increase.

According to these data, changes in medication rituals do not produce a measurable alteration in attendance patterns of chronic schizophrenic patients. A trend suggests that there may be a relationship between medication change and attendance for some patients, but a recheck of charts for evidence of this relationship produced no definite examples. It was noted that even extreme disagreements over medication seldom upset an attendance pattern.

CASE REPORTS

Case 1. A 39-year-old Mexican-American housewife had been on a stable drug routine (50 mg of chlorpromazine three times a day and 100 mg at bedtime) for many months. Her physician made a change without warning her (he substituted 5 mg of thiothixene three times a day and then increased it to four times a day after four weeks). She objected to this change often; after two and a half months she demanded that her medication be changed back again. Her doctor talked her out of this, noting that he "convinced her to try one more week." He recorded no evidence of impending decompensation.

The next notation on this chart, made three weeks later, revealed that she had been in the state hospital for 14 days and was then on a third regimen (200 mg of thioridazine at bedtime and 50 mg of doxepin twice a day). This regimen was continued at the clinic with little discussion. Follow-up at one year showed her to be improved in the judgment of the therapist.

It would be highly speculative to posit that the decompensating stress for this woman was the disagreement she had over her medication. Clinically it appears possible. However, the only time she did not attend her group was during her hospitalization.

Case 2. A 33-year-old single black woman had a fairly marked ongoing disagreement over her medication and yet continued to come to her group regularly. After many months of the same regimen her doctor discontinued her medication (100 mg of thioridazine daily) with notation, "No clear evidence of psychosis."

Two weeks later she demanded her medication and was given a small dose, discontinued again later because her doctor felt it was not indicated. At six weeks she requested a new doctor. At two months she claimed to be "desperate and in great need of her medication." At three months she claimed olfactory hallucinations. At four months a neurological workup was done; the results were normal. At five months she described fantasies of people following her and demanded that the doctor tell her what the problem was and treat her for it. He began medication (10 mg of thiothixene three times a day), and her clinical course smoothed out.

This case demonstrates evidence of a substantial stress related to medication changes as well as a decompensation, possibly as a result of loss of maintenance drug; yet this patient's attendance pattern remained unchanged.

The changes in attendance patterns of these two patients appeared to be related to a variety of factors. Other charts revealed that some patients were told to come less frequently and complied. Most of the upsets noted appeared to be related to outside events that were described when the patient returned to the group.

CONCLUSIONS

Upsetting long-standing medication rituals has been shown to have little effect on the attendance of stabilized chronic schizophrenic patients as a group. Clinicians should exercise judgment in changing medications, but it certainly appears safe to do so. Patients often see medication reviews as evidence of therapist enthusiasm and interest and as cause for new hope. Therapists who make no changes in medication routines because of patient fragility should reconsider this policy to be sure they are not rationalizing their own wishes to keep their interaction with patients unmolested and unbothersome. Certainly, because of the occasionally permanent side effects of antipsychotic medications, long-standing drug regimens must be reevaluated periodically. This study shows that medication changes are tolerated by schizophrenic patients. To paraphrase Bergin's comment on psychotherapy as a whole (40), manipulation of the medication routines of chronic schizophrenic patients makes them better as well as worse, producing little change in the group when viewed as a whole.

A Psychiatric Study of Patients Referred with a Diagnosis of Hypoglycemia

BY CHARLES V. FORD, M.D., GEORGE A. BRAY, M.D., AND RONALD S. SWERDLOFF, M.D.

Five-hour oral glucose tolerance tests (GTTs) differentiated 30 volunteer patients who considered themselves hypoglycemic into three major groups: those who had reactive hypoglycemia, those who were normal, and those who had diabetes. Clinical psychiatric evaluation and Minnesota Multiphasic Personality Inventory testing revealed that half of the 30 patients were experiencing a current psychiatric disorder, usually depression. Hysterical personality traits were also noted in many of the patients. The idea that reactive hypoglycemic patients have specific personality characteristics was not substantiated by the authors' data. They hypothesize that some patients with psychiatric illness may have their symptoms erroneously attributed to incidental GTT findings.

IN RECENT YEARS there has been considerable popular interest in "hypoglycemia." Stimulated by books that implicate hypoglycemia as the cause of such diverse diseases as asthma and alcoholism, many people have become preoccupied with glucose tolerance tests, special diets, and unproven therapeutic modalities. Popular medical books (1–3) purport that any psychological discomfort may be secondary to metabolic problems that are treatable by diet.

Opposed to the view that psychological symptoms may result from hypoglycemia is the work of some early investigators (4–6) suggesting that hypoglycemia itself may be an effect of tension and anxiety. Other writers, while not offering opinions as to etiology, have commented that hypoglycemic patients are often intense, driving, and conscientious (7), tense and emotionally labile (8), and nervous and apprehensive (9) and that they experience exacerbations of symptoms during periods of emotional tension (10). There are few systematic psychiatric descriptions of hypoglycemic patients in the literature, although some case histories have been reported (4, 5). Most communications have made use of such general terms as "emotional tension" and "strain." There is considerable cross referencing among these descriptions.

In a 1973 study, Anthony and associates (11) administered the Minnesota Multiphasic Personality Inventory (MMPI) to a number of patients who were considered hypoglycemic according to glucose tolerance tests. Their findings indicated that, regardless of the cause of the hypoglycemia, the patients had MMPI scores compatible with significant hypochondriacal and hysterical personality features. They suggested the possibility that reaction to the hypoglycemic symptoms could cause this personality pattern, although they acknowledged that a definitive statement as to causality could not be made on the basis of these data.

Because of the widespread belief that emotional distress in many people is causally related to low blood sugar, we conducted a pilot study to define the psychological status of people purported to have reactive hypoglycemia.

METHOD

We advised local practicing physicians that patients diagnosed as hypoglycemic could be hospitalized at no cost to the patient in the Clinical Study Center of Harbor General Hospital for a detailed medical workup. Although we told potential patients that an assessment of their psychological status would be made during their admission, we made no effort to recruit patients with psychiatric symptoms. Thirty people volunteered to take part in the study. They were instructed to maintain a high-carbohydrate diet for several days before admission to the hospital, where they stayed for an average of five days.

A five-hour oral glucose tolerance test (GTT) was

The authors wish to thank Robert R. Rubin, M.D., for valuable suggestions in the preparation of this paper.

obtained on the second day of hospitalization. Venous blood samples were obtained 30 and 15 minutes before the test, at the start of the test, and at 10, 20, 30, 40, 50, 60, 75, 90, 105, 120, 135, 150, 165, 180, 210, 240, 270, and 300 minutes during the test. Blood samples were frozen, and analyses were not made until after the psychiatric and psychological opinions were obtained. Thus the psychiatric interviewer had no knowledge of the presence, type, or extent of each patient's hypoglycemic response. Serum glucose was determined by the glucose oxidase method. (Because numerous factors influence the glucose tolerance test [12], we arbitrarily used the GTT under standardized conditions to define the presence or absence of a hypoglycemic response.)

Multiple biochemical determinations of hormones and other metabolic substances involved in glucose homeostasis were also made; the results of these studies will be reported elsewhere. This paper will be concerned with the psychological evaluations of 30 patients who referred themselves to our clinical center because they thought they had hypoglycemia and the relationship of their psychological findings to their glucose tolerance curves.

The clinical sample was composed of 22 women and 8 men. The age range was 20 to 67 years, with an average of 37.6 years. All of the patients were Caucasian and of middle-class socioeconomic status. Most were employed or functioning as homemakers. Four had never married, 4 were divorced, and 6 had been married two or more times. All of the patients regarded themselves as medical patients and considered their distress to be caused by hypoglycemia. Ten patients (33%) had received some type of psychiatric treatment in the past.

The patients were seen for a nonstructured interview that lasted from one to one and a half hours. They also completed the MMPI and a symptom questionnaire that asked about symptoms commonly attributed to hypoglycemia. From these data, using standard nomenclature and diagnostic descriptions, the patient was assigned a current reactive psychiatric diagnosis and a personality diagnosis when applicable. The psychiatric and psychological data were then grouped and compared according to the patients' GTT diagnoses.

There is recognized difficulty in defining the dividing line between normal and hypoglycemic glucose tolerance curves. Different investigators may choose different nadirs on the GTT to define hypoglycemia. Consistent with values used by local practicing physicians, we arbitrarily used a nadir of below 65 mg/100 ml to define hypoglycemic. However, because controversy exists as to what constitutes a hypoglycemic level, the MMPI data were also analyzed using Spearman's rank correlation coefficient to relate the severity of the hypoglycemia to the degree of MMPI abnormality on three clinical scales (depression, hysteria, and psychasthenia). We hypothesized that by this means any relationship between symptoms and blood sugar concentration would be demonstrated irrespective of the value used to define hypoglycemia.

RESULTS

Glucose Tolerance Tests

Despite the fact that all of the patients reported that they had had glucose tolerance tests in the past that diagnosed hypoglycemia, not all of the patients demonstrated hypoglycemia during our standardized test. Patients were placed into the four following different groups on the basis of their GTTs: patients with reactive hypoglycemia (normal GTT, except for one or more values below 65 mg/100 ml during the test); those who were diabetic (elevations of glucose that met the definition of diabetes of the U.S. Public Health Service [13]); those who were normal; and those who were atypical. Eighteen patients were diagnosed as having reactive hypoglycemia, 7 patients had a normal GTT, 4 were diabetic, and 1 patient had fasting hypoglycemia (later diagnosed as secondary to an insulinoma; this patient was considered atypical). The nadirs on the GTTs of the reactive hypoglycemic patients occurred between 75 and 270 minutes of the five-hour test. The mode at which their nadirs occurred was 210 minutes. Two of the diabetic patients and the patient with an insulinoma also had at least one hypoglycemic value. The distributions of the times and the extent of the glucose nadirs during the GTTs are indicated in table 1.

Reported Symptoms

The patients usually reported histories of multiple symptoms. Symptoms reported at least 50% of the time by the entire group included emotional lability, depression, headaches, diaphoresis, tremor, tachycardia, weakness, dizziness, and difficulty thinking. Other

210–240	8	2	0
270–300	4	2	3

symptoms reported by 25% or more of the group included nausea, hunger, fatigue, visual disturbances, transient neurological symptoms, and syncope. Each patient complained of an average of 8.6 symptoms. There was no correlation between degree of hypoglycemia and number of symptoms reported (r=.059).

Psychiatric Interview Data

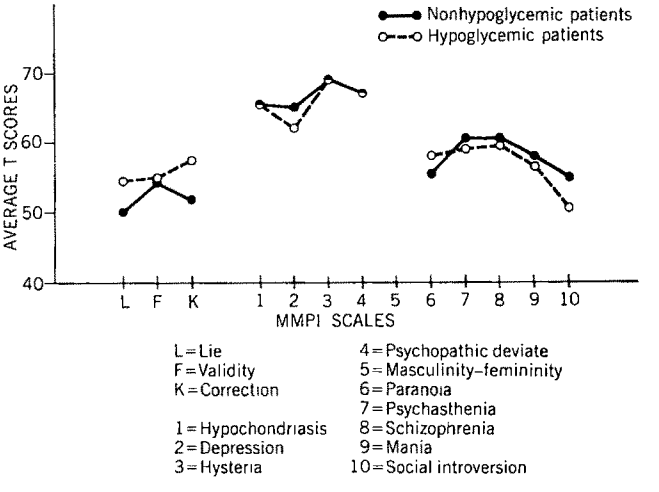
Many of the patients appeared to be experiencing acute emotional distress. However, they denied this distress or attributed it to somatic problems; they displaced their psychological discomfort to concerns and preoccupation with physiological processes. Their personal histories revealed a close relationship between the development of the symptoms and external precipitating stress, e.g., marital discord, separation, divorce, job change, and the death of a close relative.

Some of the symptoms reported, such as sleep disturbance, were compatible with a primary psychiatric disorder. Fifteen of the patients (50%) were judged sufficiently symptomatic (in the interview and according to self-reports) to establish an acute psychiatric diagnosis. Latent problems were suspected in patients who were not formally diagnosed (diagnostic criteria were conservative). Ten patients were considered to have a depressive neurosis, 3 an anxiety neurosis, 1 schizophrenia, and 1 a psychophysiologic reaction (headaches). The distribution of the clinical diagnoses according to the patients' GTT diagnoses is shown in table 2. The numbers are too small for meaningful statistical analysis, but it is interesting to note that all three diagnoses of anxiety neurosis occurred in the reactive hypoglycemia group.

In addition to establishing acute psychiatric diagnoses, we made an effort to document the patients' personality structures on the basis of lifelong characteristics, not just the manner in which the patient responded to his or her current ailment. An unhealthy personality pattern was identified in 19 of the 30 patients. The other 11 were regarded as having an essentially normal or healthy personality. Hysterical personality (12 women, 2 men) was the predominant personality type diagnosed. There was no demonstrable relationship between personality type and GTT diagnosis (see table 2).

Characteristics used in diagnosing a hysterical personality included dramatization of life events, conflicts in sexual identity, narcissism, and immature dependence on others. Characteristics used to define an obsessive-compulsive personality included emotional rigidity, excessive worry and attention to detail, inhibition, and marked conscientiousness.

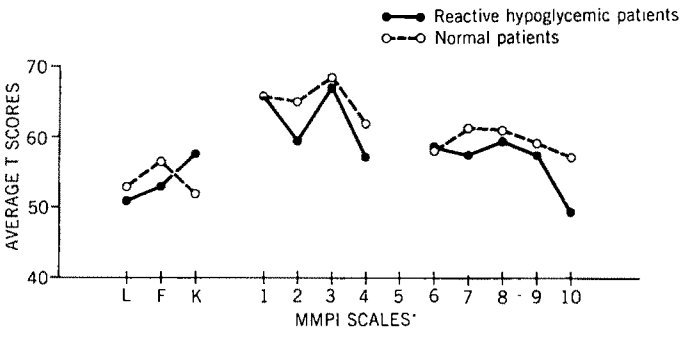
MMPI Data



The MMPIs of 18 of the 30 patients were interpreted as abnormal, i.e., their T scores exceeded 70 (2 standard deviations above the norm). Another 9 patients had an elevation greater than 65 on at least one T score, placing them in a borderline abnormal group. The most typical profile was one that contained the "conversion V," in which the scores for scales 1 and 3 (hypochondriasis and hysteria) were at least one-half a standard deviation higher than the score for scale 2 (depression). This MMPI configuration is often associated with hysterical complaints (14, pp. 86–116). Ten of the 21 hypoglycemic patients showed the "conversion V," and 2 of the 9 nonhypoglycemic patients demonstrated this profile (the difference was not statistically significant).

Averaged MMPI T scores failed to distinguish the hypoglycemic group from the nonhypoglycemic group (see figure 1). Average MMPI T scores for the reactive hypoglycemic patients compared with those of patients with normal GTTs also did not show significant differences (see figure 2).

TABLE 2
Distribution of Psychiatric Diagnoses and Personality Patterns of 30 Patients, by GTT Diagnosis



Item	Number of Patients, by GTT Diagnosis		
	Reactive Hypoglycemia (N=18)	Normal (N=7)	Diabetic and Atypical (N=5)
Psychiatric diagnoses			
Anxiety neurosis	3	0	0
Depression	6	2	2
Schizophrenia	0	1	0
Psychophysiologic reaction	1	0	0
Personality patterns			
Hysterical	10	2	2
Healthy	5	3	3
Obsessive-compulsive	3	1	0
Inadequate	0	1	0

FIGURE 1
Comparison of Average MMPI Scores of All Hypoglycemic Patients (N=21)* and All Nonhypoglycemic Patients (N=9)**

* The glucose nadirs of these patients were below 65 mg/100 ml.
** The glucose nadirs of these patients were above 65 mg/100 ml.

FIGURE 2
Comparison of Average MMPI T Scores of Reactive Hypoglycemic Patients (N=18) and Normal Patients (N=7)

* See figure 1 for MMPI scales.

The type of average profile obtained for our 30 patients is consistent with that for people having hysterical personality traits with conversion symptoms. Denial, repression, and somatization have been suggested as defenses against underlying depression and/or anxiety (14, pp. 158–214).

Comparison of the degree of GTT abnormality (as measured by the serum glucose nadir) with the individual MMPI scales of depression, hysteria, and psychasthenia yielded no correlation. All values, as computed by Spearman's rank correlation coefficient, were close to 0.

DISCUSSION

The terms "reactive hypoglycemia" and "functional hypoglycemia" are generally used to describe patients with postprandial hypoglycemia in whom an abnormality of one of the organs of glucose homeostasis is not demonstrable. There are many causes of fasting and postprandial hypoglycemia (15), including such potentially serious disorders as islet cell tumors, adrenal and pituitary insufficiency, severe liver disease, and alcohol-induced hypoglycemia. Other recognized causes of postprandial hypoglycemia include those related to altered gastrointestinal structure and physiology (alimentary hypoglycemia) and the hypoglycemia of early adult-onset diabetes.

Of the many categories of hypoglycemia, functional hypoglycemia has preoccupied the interest of the popular writers. Many physicians advise their patients that an alteration of dietary intake and habits can have a favorable effect upon symptoms. There is a rationale for attributing psychologic symptoms to hypoglycemia (15).

The symptoms of hypoglycemia can be divided into two general pathophysiologic causes. The first, cerebral glycopenia, can cause neurological symptoms that include obtundation of consciousness proceeding to coma, dysarthria, visual disturbances, paresthesia, and other symptoms of central or peripheral nervous system dysfunction.

A second set of symptoms is referrable to a different physiologic process (hyperepinephrinemia). Following heavy intake of sugar or carbohydrate there may be excessive release of insulin. Insulin results in increased glucose utilization and a falling blood sugar. In response to decreasing blood sugar concentrations, a number of counterregulatory hormones (epinephrine, cortisol, glucagon, and growth hormone) are secreted; these act to return blood sugar concentrations toward baseline levels. Hyperepinephrinemia produces generalized physiological effects that include flushing, diaphoresis, tachycardia, tremor, pallor, and a subjective sense of weakness and anxiety. Patients may also complain of nonspecific symptoms, e.g., headaches, nausea, abdominal pain, hunger, fatigue, and dyspnea.

Given these symptoms and their relationship to carbohydrate intake, there is a possibility that a person suffering from what appears to be emotional distress may have a metabolic disturbance treatable by adherence to a low-carbohydrate diet. Logically, the severity of symptoms should be related to the degree of reactive hypoglycemia.

CONCLUSIONS

Our data do not support the proposition that the emotional distress experienced by hypoglycemic patients is due to their hypoglycemia. Neither the number of symptoms nor the severity of psychological distress (as measured objectively by the MMPI) was related to the degree of hypoglycemia demonstrated in our sample of 30 patients.

What is remarkable in our findings in these patients, who all believed that they suffered from reactive hypoglycemia whether they did or did not, was the similarity in their reported symptoms, psychiatric diagnoses, and MMPI scores. Our MMPI data for the hypoglycemic patients are in agreement with those obtained by Anthony and associates (11), but these authors found differences between hypoglycemic patients and a control group (hospitalized patients with endocrine abnormalities). Their conclusion that hypoglycemia may specifically lead to the development of hysterical characteristics is intriguing, but it cannot be substantiated by our data. We found no difference between patients who were hypoglycemic and those who thought they were hypoglycemic.

While suggesting that many hypoglycemic patients are hysterical, our data also indicate that some hypoglycemic patients are obsessive and that others have no discernible psychiatric disorder. We also found that some people who believe themselves to be hypoglycemic are hysterical but have no demonstrable hypoglycemia. Landmann and Sutherland (16) studied a group of psychosomatic patients and also found a high percentage of hypoglycemic patients but no relation-

ship between symptoms or personality characteristics and hypoglycemia.

What may be in question here is not so much whether hypoglycemia is specifically related to certain psychiatric syndromes but what type of patient is more likely to be referred for study of hypoglycemia. Both hysterical and obsessive patients are often concerned with somatic complaints. In the search for the etiology of their symptoms many laboratory procedures, including a GTT, may be performed. In an effort to establish a diagnosis, all of the patient's complaints may be mistakenly attributed to hypoglycemia, although, in essence, what brought the patient to the physician were symptoms of depression or anxiety. The finding of a reactive hypoglycemic glucose tolerance curve may be more of an incidental finding than the basis for etiology of the patient's symptoms (17).

This formulation does not negate the concept of hypoglycemia as a real entity that can express itself in multiple ways and cause genuine somatic discomfort. Rather, we would emphasize that the numerous nonspecific somatic complaints of hysterical and obsessive patients may be overdiagnosed as hypoglycemia, while more psychologically normal individuals may tolerate the symptoms of hypoglycemia with less anxiety and therefore be less likely to seek medical attention.

This hypothesis is consistent with reports that it is not uncommon for a nonsymptomatic volunteer subject to have a GTT with some markedly low values (18, 19). In the report of Park and associates (19), 23% of an apparently normal population had blood sugar levels below 50 mg/100 ml during a standard five-hour GTT. Another article (20) also stressed the epidemic nature of "nonhypoglycemia" and the number of people who now regard themselves as hypoglycemic without demonstrable GTT abnormality. Some of the patients in our sample of 30 appeared to fall into this category.

Another consideration is whether the anxiety and depression experienced by a patient with a psychiatric disorder affects glucose tolerance. However, our data demonstrate no relationship between depression and anxiety (as measured by the MMPI) and degree of hypoglycemia. Herzberg and associates (21) were also unable to demonstrate a relationship between depression and glucose tolerance.

Fabrykant (22) noted that the hyperglycemic effect of low-carbohydrate diets is limited to the first hours of the GTT and that the magnitude of the hypoglycemic response after carbohydrate restriction may exceed the response in controlled tests after standard high-carbohydrate diets. Therefore, people who believe themselves to be hypoglycemic may treat themselves with low-carbohydrate diets and then have their self-diagnosis "confirmed" by a five-hour GTT. Fabrykant recommended that one not be too quick to ascribe symptoms to hypoglycemia because of the danger of overlooking a more serious illness. The findings of our study suggest that one serious illness that can be easily overlooked is depression.

This pilot study, which used volunteer subjects who believed themselves to have reactive hypoglycemia, uncovered significant psychopathology but no intersubject relationship between the severity of psychiatric symptoms and the degree of hypoglycemia. Because of the popular interest in hypoglycemia and the potential of misdiagnosis of psychiatric illness, further research is indicated. Use of large numbers of randomly selected subjects not already identified as patients would be desirable but methodologically difficult because of such factors as the need for informed consent.

Family and Character Change at Buffalo Creek

BY JAMES L. TITCHENER, M.D., AND FREDERIC T. KAPP, M.D.

Psychiatric evaluation teams used observations of family interaction and psychoanalytically oriented individual interviews to study the psychological aftereffects of the 1972 Buffalo Creek disaster, a tidal wave of sludge and black water released by the collapse of a slag waste dam. Traumatic neurotic reactions were found in 80% of the survivors. Underlying the clinical picture were unresolved grief, survivor shame, and feelings of impotent rage and hopelessness. These clinical findings had persisted for the two years since the flood, and a definite symptom complex labeled the "Buffalo Creek syndrome" was pervasive. The methods used by the survivors to cope with the overwhelming impact of the disaster—first-order defenses, undoing, psychological conservatism, and dehumanization—actually preserved their symptoms and caused disabling character changes.

On February 26, 1972, an enormous slag dam gave way and unleashed thousands of tons of water and black mud on the Buffalo Creek valley in southern West Virginia. This Appalachian tidal wave destroyed everything in its path, killing 125 people and leaving 4,000 homeless and carrying away human bodies, houses, trailers, cars, and other debris. It expended its force in no more than 15 minutes at any one point in the 18-mile-long valley.

Just below the dam and the tipple of the Buffalo Mining Company stood the town of Saunders; there was no trace of this town minutes after the black water broke through the dam. The sides of the valley are steep at this point, and the wall of water and mud caromed from side to side, miraculously sparing some homes but destroying many others as it slammed down the valley.

The wall of water sped through 14 mining hamlets with names like Crites, Becco, Lundale, and Pardee, hitting their schools, churches, taverns, stores, and homes, leaving no trace of some and damaging nearly all. The sides of the valley become less steep and it spreads out, so the black sludge and water became more of a "flash flood" at Amherstdale and just an overflow at Man, where it reached the Guyandotte River.

None of the settlements in Buffalo Creek, which had a total population of 4,000–5,000 inhabitants, were incorporated. There was no governmental organization beyond the commercial structures provided by post offices, schools, and churches. There are five deep mines in operation and evidence of stripmining is everywhere. In spite of the stripping, the ugly tipples, the dozen or so huge black heaps of waste, the railroad and highway construction, it is still a beautiful valley, and young adults there will tell you it was once much more beautiful, with pleasant homes and gardens where there are now primarily mobile homes. It was and is a middle-class area. Nearly all families are supported by employment in the coal mines or in the supporting industries and services. There is an accepted (but not documented) belief that this valley had not had the degree of emigration of young people that typified others like it since the Depression.

There had been rumors for years that the dam would give way, but hundreds of people reported they did not believe it had really happened until a few moments after the fearsome sight and sound of the advancing water. All the survivors know that the time of the dam break (8:00 a.m. on a Saturday morning) was fortunate. Few people were down in the road, and the children were not in or waiting for the school buses. Nevertheless, 125 were killed, and most lost their homes and possessions.

Subsequently, a group of 654 survivors of this disaster from 160 families began a legal action against the

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

company that owned the dam. This group contacted the law firm of Arnold & Porter in Washington, D.C., and a legal team headed by Mr. Gerald Stern traveled to the area to interview survivors. His observations of the psychological effects of the disaster and a summary of the litigation are presented in "From Chaos to Responsibility" in this section. The law firm first contacted Robert J. Lifton, M.D., who assessed "The Human Meaning of Total Disaster" (1), and Kai Erikson, Ph.D., whose observations of the situation in the community are presented in "Loss of Communality at Buffalo Creek." The suit was settled in July 1974 for $13.5 million of which $6 million was for psychological damages.

The legal team then retained one of us (J.L.T.) to organize a group of experts to interview the survivors and assess for the court the psychological impairment they had suffered as a result of the flood. This paper presents our findings on the severity and duration of these psychological effects, a symptom complex we have labeled the "Buffalo Creek syndrome." The size and composition of the evaluation teams varied with the nature of the families assigned to them. A full-sized team consisted of a general psychiatrist, a child psychiatrist, and two psychologists or case workers. These teams did their work in the valley itself, visiting the respondents' mobile homes and those houses that were still standing.

We conducted a pilot study consisting of interviews of 50 survivors in June of 1973. The court then directed that all of the survivor-plaintiffs be interviewed, as all were bringing suit separately. These evaluations were carried out on several long weekends in the spring of 1974.

We began each evaluation with a family interview in which we asked the survivors to talk about their experiences on the "day of the black water" and during the weeks and months that followed. As they talked, we were able to see beyond the immediate clinical phenomena to these people's underlying feelings and their ways of coping with them. The family sessions were followed by psychoanalytically oriented individual interviews with each family member, conducted in backyards, living rooms, or on porches.

EVALUATION FINDINGS

Disabling psychiatric symptoms such as anxiety, depression, changes in character and lifestyle, and maladjustments and developmental problems in children were evident more than 2 years after the disaster in over 90% of the individuals we interviewed. We asked ourselves whether we were examining people who were presenting major symptomatology and character problems that resulted from basically weak ego structures and who were using the disaster in order to win a large settlement from the mining company. Our answer was and is "no." In our evaluations, we witnessed difficult and prolonged struggles with powerful feelings and ideas aroused by the traumatic experience of the disaster and the very uneven attempts of the survivors to reorganize themselves and redevelop shattered coping and adaptive mechanisms. The affects associated with the catastrophe and its aftermath, as well as the psychological and social ways these people chose to deal with them, must be seen against the background of the universal crises of human development. The attendant threats of separation, abandonment, castration, and death—residuals of the developmental crises of separation and individuation—provided the context for the meaning of the catastrophe to the survivors (2, 3).

We found a definite clinical syndrome in the survivors of the Buffalo Creek disaster that arose from both the immediate impact of the catastrophe on each individual and the subsequent disruption of the community and that affected everyone living there. We are all predisposed by previous experiences to be traumatized by pathogenic forces as destructive and awesome as the Buffalo Creek catastrophe. Variations in the clinical picture resulted from individual differences in modes of processing and reorganizing the traumatic experience (4).

A clear pattern emerged from our evaluations and analyses. A traumatic neurotic syndrome was diagnosed in more than 80% of the survivor-plaintiffs, and changes in character structure were equally widespread. These changes, although they were attempts at readjustment, occasionally resulted in maladjustment in the social sense and always went in the direction of psychologically disabling limitations.

Character changes represent the stabilizing neurosis, the psychologically hardening and fixating consequences of the catastrophe. We found conscious and latent meanings and understandings and misunderstandings of the disaster and its aftermath, all of which were associated with the feelings and conflicts aroused by the trauma. The result of this was changes in object relations and attitudes toward the self. We delineated various processes of reorganization—attempts at putting personality functions back together—that were directed toward reintegration and resumption of a nontraumatized life.

We shall indicate below how this personality reorganization, which was so aimed at prevention of recurring experience of the traumatic state, actually *interfered* with flexible and effective recovery and thus preserved symptom patterns and forced changes in the way of life.

SYMPTOMS AND CHARACTER CHANGES

During the first days and on into the weeks and months after the disaster, the survivors reported disorganization and sluggishness in thinking and decision making. They complained of having difficulty controlling their emotions. These problems ranged from emotional outbursts to the simple inability to feel any-

thing. Some described transient hallucinations and delusions. Almost all reported anxiety, grief, and despair, with severe sleep disturbances and nightmares. Later, the anxiety was manifested in obsessions and phobias about water, wind, rain, and any other reminder that the disaster could recur. Occasionally these obsessive disturbances coalesced and became a group phenomenon. For instance, the wife of a community leader never slept when he was asleep so that one of them would always be on the alert. On rainy nights, this man received phone calls regarding rumors that another dam was about to give way. He would then take his rifle and spend the night sitting on the supposedly weakened dam, guarded by others to protect him from attack.

Grief over the loss of relatives, friends, possessions, and mementos such as family Bibles, as well as the loss of the feeling of communality discussed by Dr. Erikson, was widespread. For many, unresolved grief turned into depressive symptoms, ideation, and behavior, and some developed a depressive lifestyle (5). In some individuals, depression was channeled into a wide range of somatic complaints, with probable increases in the incidence of duodenal ulcer and hypertension.

Many of these people have become listless, apathetic, and less social since the disaster. They cling to their families, lack ambition, and are disinterested in former hobbies and sports. These changes have led to an overall limitation of essential expression, a lack of zest for work and recreation, and despair about ever again resuming the lifestyle they once had.

THOUGHTS, FANTASIES, AND FEELINGS AROUSED BY THE DISASTER

The survivors referred to the disaster as "the end of time" or "the end of everything," and noted that "No one who was not there could ever really know what happened." They were haunted by visual memories and emotions associated with the drownings of relatives and friends and of blackened bodies and parts of bodies that were uncovered for weeks after the flood.

All of the survivors had to confront the loss of a sense of personal invulnerability. The former feeling of comfort and assurance about the continuity of life had depended partly on magical beliefs that horrible things like this disaster do not happen to one; that they could not occur in nice sane communities in this country. Then the impossible happened. The shock was overwhelming and a new outlook took form that reflected a swing from the former sense of invulnerability to pessimism, emptiness, and hopelessness. We heard such comments as "Nothing counts anymore"; "What's the use now?"; and "Since we lost everything, what's to be gained by trying?" The disaster took on the meaning of chaos, helplessness, and death, giving rise to feelings of personal insignificance.

Three other reactions contributed to depressive symptoms and lifestyles. The first was a feeling of impotent rage over the destruction to life, property, and a way of life. This rage is an explosion of feeling against the attack on the self. The victim has little outlet for his anger or hope of satisfaction. This feeling had special intensity because the destruction in Buffalo Creek was man-made; it was caused by the inexplicable inhumanity of a powerful corporation that gave terrible evidence of not caring about its employees or their community. The survivors' guilt was expressed in a wide variety of derivative feelings about the self, in symptoms, in character change, and in behavior through self-denial and lack of hope. These conflicts were not resolved, and their persistence took form in identification with the dead in dreams, actions, and attitude toward life (6).

No one behaves exactly as he thinks he should in a hazardous situation, particularly in a situation he is powerless to influence. Memory becomes clouded and feelings of helplessness influence the way one looks back on the traumatic event. Many people in Buffalo Creek manifested "survivor shame." One of the actual heroes of Buffalo Creek, who had been extraordinarily effective in mobilizing and leading rescue efforts, was able to fend off depression and anxiety in the first four weeks after the flood while he worked relentlessly to help others. When he attempted to return to his former work, he was overwhelmed by anxiety and depression connected with feelings of inadequacy. He developed a phobia connected with his job, began drinking heavily, and became clinically depressed.

We noted in many people a sense of isolation and feelings of alienation combined with an increased need for vigilance and a tightening of the ring around the family. Former feelings of self-assurance, sociability, trust in neighbors, and enjoyment of community activities disappeared. The isolation we observed clinically can be explained by the depressive reactions, the chronic anger, the loss of a way of life, and the dissolution of self-confidence and basic trust.

It has been hypothesized that the emotional disturbances aroused in the victims of disaster quickly disappear after the stress has subsided. Our work at Buffalo Creek suggests that this is rarely the case; the manifestations of a traumatic neurosis do not subside with the receding flood waters. The effects may seem to disappear quickly if one is not alert to the subtle covering-up behavior of the victims of a psychic trauma.

Lifton and Olson (1) explain the persistence of traumatic effects on the basis of an analysis of the nature of the disaster itself and the special psychological effects of such an experience. Our study complements their work by showing how the effects of a traumatic event are preserved by the modes of adaptation to overwhelming fears and hopelessness. The very attempts to protect self, family, and community from a recurrence of helplessness and loss are responsible for the individual and societal neurosis and restrictive character change. Our combined approach has been to show what occurred, the nature of its impact on the psyche,

and why its effects became chronic.

One can analyze the sequential formation of the "Buffalo Creek syndrome" as follows. The disaster activated intense affects, including fear, rage, and helplessness. These waves of external and internal overstimulation overran the stimulus barrier and the ego's capacity to integrate the traumatic experience and control and discharge the affects. There was temporary ego collapse and the ego was damaged. We estimate that reorganization of the ego in whole or in part required 6 to 24 months. The course of the reorganization and the way individuals processed these affects, memories, and the associated conflicts made the ultimate difference in outcome. The survivors' course of ego reorganization and their manner of processing the disaster experience were reflected in their symptoms and character change (2, 4, 7, 8). The variables in the reconstitution of the personalities of the survivors we studied can be divided into four categories.

PERSONALITY RECONSTRUCTION

First-Order Defenses

There was a continuous and steady deployment of a coordinated system of character-shaping first-order defenses (9), i.e., projection, externalization, and denial. Projection defended against feelings of guilt and shame aroused by the disaster. The constructors of the dam, state and federal agency representatives, and intrusions from the society outside of the valley became objects of increasing anger and fear. Externalization blocked awareness of this anger and fear as well as feelings of helplessness. Individuals became sensitive to and acutely observant of the anxiety and unrest in their families, coworkers, and the social group. Denial defended against recognition that the self had been changed in any way; it disavowed the feeling of helplessness and the awareness of psychological scarring (10). Denial enabled people to believe that while much had happened to them and to those around them, they had not been affected in an *essential* way, and that they were the same people they had been before the flood. This defensive complex protected against emotions that would have otherwise reactivated memories and feelings of fright and helplessness. It was oriented to the present and functioned continuously, preventing the gradual recollection and discharge of the feeling of helplessness and blocking recognition of the irrationality of shame and guilt. Although one can never be the same after an experience with disaster, this defensive system provides a desperate sort of status quo that substitutes for personal regrowth.

Efforts to "Undo" the Disaster Experience

Undoing consisted of efforts to change the past by reliving the disaster in dreams and other ways, giving it a different outcome. Survivors' memories of the early postdisaster period contained fantasies of magical reliving of childhood stresses. Attempts at undoing also appeared in strange, symbolic reenactments of the trauma, sometimes leading to violence to the self or others. Freudian repetition compulsion was often replaced by the mechanism of undoing, which is a defense against facing the anxiety associated with the trauma.

The dreams of the survivors during the period of initial shock and (in many cases) for months thereafter were fantasied attempts to relive the disaster, but with a less painful outcome. At first, such dreams were unsuccessful and people awoke from them in terror. As time passed, the dreams were modified. Although the affects remained frightening, the subject matter shifted from the flood to previous, often long-past, images of chaos and threats of annihilation. The dreams no longer involved direct reliving of the disaster but instead depicted stressful episodes that represented repetitions of normal developmental crises such as separation, abandonment, castration, and guilt (1, 8).

The regressive process in these traumatic neuroses differs from that in other psychoneuroses. The goal is not gratification or mastery of infantile conflicts, but rather an attempt to work through recent traumatic anxiety. The anxieties of infantile and childhood phases of personality development become the focus of undoing because these problems had been successfully contained or overcome; dreams of long-past stresses that had been mastered provided reassurance to the survivors that they could overcome the recent trauma. Just as "examination dreams" attempt to deal with anticipatory anxiety by fantasying a past stress that had been overcome, dreams that are characteristic of traumatic neuroses attempt to neutralize the overwhelming anxiety of the traumatic event by recalling successful past adaptations to difficult situations. Each of these phases of dealing with normal stress, reproduced in the survivors' dreams, is common to all persons as part of human epigenesis. Each past crisis included not only a deprivation of instinctual demand but also a threat to the continuity of life. The latter aspect is what makes them particularly suitable for undoing the threat of annihilation experienced in a trauma like the Buffalo Creek disaster.

Because undoing relies on omnipotence and magic, it prevents recognition of the influence of guilty, shameful attitudes toward the self. The undoing process—aimed at fending off fearful anticipation of a recurrence of the traumatic experience—is a continuing obstacle to the relatively nonanxious acceptance of human vulnerability that is necessary for readaptation.

The Psychological Emphasis on Survival

Psychological conservatism consisted of avoidance of situations that might raise the level of excitation either internally or externally. It is the defensive and ego psychological counterpart of the psychic numbing described by Lifton and Olson (1). We perceive psychic conservation as mental activity designed to control behavior by banking energies, surrendering ambition, reducing enthusiasm, dampening socializing and love-

making, and discouraging novel experience (11). Psychological conservatism accepts survival as the only goal of existence. It is a trade-off: the individual accepts hopelessness in the present to prevent helplessness in the future, as if to say, "Better to live without hope than not to live at all." Psychological conservatism functions as if the disaster will recur tomorrow, thus totally distorting an individual's view of the future. If you live as though the dreaded uncertainty is certain to occur, you become a psychic conservative.

Dehumanization

Dehumanization affects one's view of life and human relationships and has a direct toxic effect on personality function. Every disaster places man at the mercy of forces beyond his control. The feeling of being a pawn of fate is dehumanizing—people feel without appeal, beyond empathy, and cannot be persuaded or assuaged. When the catastrophe is man-made, dehumanization is magnified. In Buffalo Creek, there was the terrible realization that other human beings had planned, built, and maintained an unsound dam and then acted irresponsibly and uncaringly after the resulting disaster. The defense of dehumanization is an example of identification with the aggressor. It destroyed pride and joy in being human.

Dehumanization may be mitigated by corrective experiences with empathic people in the helping professions and private and public institutions. Collaboration with other sufferers in a law suit against the dehumanizing aggressor may also be useful in that it can ensure that it will be more difficult for such organizations to risk human life in the future.

CONCLUSIONS

It is our belief that the reactions we have described are not those of individuals with weak egos who were exaggerating their complaints in order to win a law suit. These people, by and large, did not exaggerate their complaints; the majority minimized or denied them. If their reactions were merely exacerbations of old neurotic symptoms and problems, we would have encountered a wider range of psychoneurotic reactions. Although there were differences in modes of response, the uniformity of the psychological reactions comprising the Buffalo Creek syndrome was striking. Our analyses of dreams and early memories, reported elsewhere (12, 13), support the consistency and severity of this syndrome.

We found a definable clinical entity characterized by a well-delineated group of clinical symptoms and changes in character and lifestyle that were related to clear-cut psychopathogenic factors precipitated by the disaster. All of us have in our unconscious memory systems encounters with the various forms of dread that a disaster reawakens. There need not be any preexisting neurosis for the Buffalo Creek syndrome to become disabling and chronic. All of us are susceptible to traumatic neurosis and the "death imprint."

To be successful in treating these traumatic neuroses, we must substitute active recall and working through of the painful memories of helplessness and separation for counterphobic behavior, passive reproduction of the experience in dreams, and magical ways of living out and reenacting the trauma. The change from passive to active experience, from reproduction to re-creation is the essential thing. By linking long-past and previously worked-through childhood anxieties with the overwhelming anxieties aroused by the recent disaster, we may be able to strengthen the ego of the individual with a traumatic neurosis. Through his relationship with helping and capable persons and institutions, the disaster survivor is given an opportunity for regrowth, much like the ego development that came about as the individual met and dealt with the normal crises of growing up.

From Chaos to Responsibility

BY GERALD M. STERN, L.L.B.

The litigation initiated by the 625 survivors of the Buffalo Creek flood who refused to settle with the coal company claims office was a landmark case. For the first time, individuals who were not present at the scene of a disaster were allowed to recover for mental injuries. Psychic impairment, the term coined for these injuries, was found in virtually all of the survivor-plaintiffs. In an out of court settlement, the survivors were awarded $13.5 million, $6 million of which was distributed on the basis of a point system as compensation for the psychological damages.

THE DESTRUCTION of the Buffalo Creek community gave rise almost immediately to the creation of a new kind of group—a community of 625 survivors from 160 families who joined together to sue the coal company that owned the dam. These individuals, unlike the majority of the survivors, refused to settle their cases at the coal company claims office. Instead, they sought legal help outside the state of West Virginia.

This group contacted Arnold & Porter, a law firm in Washington, D.C., and we agreed to represent them.[1] We immediately went to Buffalo Creek and spent many days interviewing survivors at Charlie Cowan's gas station, one of the few buildings remaining in the Buffalo Creek valley. Mr. Cowan was the leader of the citizens' committee that called to ask for our legal help. The survivors' legal right to sue for traditional damages was clear; they could sue for lost property, for their homes and all their possessions, for physical injuries, or for the death of family members. However, it soon became apparent that they also had significant mental injuries, and it was not so clear whether the law would permit recovery for these damages.

The magnitude and significance of these mental and emotional damages hit me personally when I interviewed a coal miner who had lost his 22-month-old son and his pregnant wife in the disaster. The flood waters caught this family asleep in their home. As the wife disappeared in the black water, she cried out to her husband to save their son. He held the child tightly and tried to struggle to safety, but houses and debris battered him and the child as they were washed miles down the valley. Somewhere in this maelstrom, he lost his grip on his son, who disappeared forever into the black waters. Eventually, this man was able to struggle to safety, although his body was badly lacerated by the jagged wood in the water. At the time I interviewed him, my own son was exactly 22 months old. I was terribly upset by his story and decided to try to expand the lawsuit to recover for his mental agony and for the mental suffering of others like him.

We contacted Robert J. Lifton, M.D., who had studied the survivors of Hiroshima. He agreed to interview a number of our clients and to help us explain to the court in lay terms the common psychiatric injuries of these survivors. He also suggested that we ask Dr. Kai Erikson, whose findings are reported in this section, to study the sociological aspects of this disaster. With these two men as our principal experts, we articulated for the court and for the coal company defendant what we called the "psychic impairment" damages suffered by every one of our survivor-clients.

We coined the term "psychic impairment" to include both the psychiatric damages identified by Dr. Lifton and the loss of communality found by Dr. Erikson. We wanted to avoid alleging that the survivors suffered mental illness and felt that the phrase "psychic impairment" had a less negative connotation.

Eventually we also employed a team of psychiatrists from the University of Cincinnati, some of whose findings are also presented in this section, to interview each of our clients. The coal company also retained a psychiatrist—actually, a physician whose primary field was neurosurgery—and a young psychologist in training, who also examined each of the 625 men, women, and children involved in the lawsuit.

Our psychiatric studies indicated that almost all of the survivors were suffering from psychiatric damage of varying degrees as a result of this disaster. In contrast, the physician retained by the coal company determined that the survivors generally suffered only transient situational disturbances that he felt should have abated soon after the disaster. The fact that the survivors still had disturbances when he examined them some 18 months after the disaster led him to presume almost invariably that these people were suffering primarily from preexisting mental conditions.

Under traditional legal principles, if the survivors had been physically injured by the flood waters and, as a result, had suffered psychiatric damages, they could recover full monetary damages unless their current

Mr. Stern is a partner in the law firm of Arnold & Porter, 1229 19th St., N.W., Washington, D.C. 20036.

[1]A much more detailed report of my observations and involvement in this case will be presented in a forthcoming work (1).

mental conditions were merely the result of an aggravation of preexisting mental conditions. Our physicians indicated that the survivors' psychiatric damages were caused *solely* by the disaster. The coal company physician disagreed. This is a dispute juries must often resolve in cases involving psychiatric damages.

The more interesting and more difficult legal question presented by this case was whether the survivors could recover monetary damages at all, even if the jury found that all of the survivors' present psychiatric injuries were caused by the disaster. Traditionally the law does not permit recovery for psychiatric injury on the sole ground that the injury can be proven to have been caused by another person or persons. For example, a mother who sees a truck run over and kill her child may suffer severe psychiatric trauma, but the law traditionally has denied the mother recovery for her own suffering, terming her a mere bystander. Needless to say, an individual who sees a friend killed has even less chance in the courts of recovering for mental suffering.

In this case, most of the survivors were not seriously injured physically. Many of them had run up the side of the valley just ahead of the flood waters, and some of them were not even in the valley at the time of the disaster. For example, one survivor was visiting in New Mexico, another was in Florida, some were in jail, and others were in hospitals in nearby towns outside the valley. Nevertheless, we insisted that all of the survivors were entitled to recover for their mental suffering, even if they suffered no physical injury, saw or heard no relative or friend in peril, or were absent from the valley on the day of the disaster. We argued that each resident of the valley, even those who were not there during the flood, was a direct victim of the coal company's reckless conduct and not merely a bystander.

The court agreed with this contention and held that all survivors—even those who were outside the valley at the time of the disaster—could collect for mental injury if we could convince the jury that the coal company's conduct was reckless (i.e., more than merely negligent), and that this reckless conduct caused the survivors' mental suffering (2).

Once the coal company realized that the court would not dismiss the psychic impairment claims of any of the 625 survivor-plaintiffs in this lawsuit, we reached a settlement for a total of $13.5 million, to be divided among the survivors by their own attorneys. We first calculated the payments for real and personal property losses, for wrongful deaths, lost wages, other miscellaneous claims, expenses, and legal fees. This left approximately $6 million to be distributed for psychic impairment. We distributed this money to the 625 plaintiffs using a point system based on their immediate involvement with the disaster, their medical disability, their loss of community ties, and the disruption of their way of life. Each survivor received between $7,500 and $10,000 after all expenses and legal fees were deducted. Approximately $2 million of the $6 million was placed directly in a trust fund for the 224 children under the age of 18 who were plaintiffs in the case.

The court's approval of this substantial monetary settlement for survivors' psychic impairment established a significant legal precedent for recovery in cases of mental suffering. The court was not bound by concepts of space and time. Instead, the court recognized that it is the permanence of loss, rather than the witnessing of the disaster, that causes mental suffering. In other words, the court (and eventually the coal company) was persuaded that the relief provided by the law should be determined not by narrow traditional legal principles but by fairly modern psychiatric and sociological principles.

Loss of Communality at Buffalo Creek

BY KAI T. ERIKSON, PH.D.

The survivors of the Buffalo Creek disaster suffered both individual and collective trauma, the latter being reflected in their loss of communality. Human relationships in this community had been derived from traditional bonds of kinship and neighborliness. When forced to give up these long-standing ties with familiar places and people, the survivors experienced demoralization, disorientation, and loss of connection. Stripped of the support they had received from their community, they became apathetic and seemed to have forgotten how to care for one another. This was apparently a community that was stronger than the sum of its parts, and these parts—the survivors of the Buffalo Creek flood—are now having great difficulty finding the personal resources to replace the energy and direction they had once found in their community.

THE TRAUMA experienced by the survivors of the Buffalo Creek disaster can be conceptualized as having two related but distinguishable facets—the individual trauma and the collective trauma.

By individual trauma, I mean a blow to the psyche that breaks through one's defenses so suddenly and with such force that one cannot respond effectively. As the other papers in this section make abundantly clear, the Buffalo Creek survivors experienced just such a blow. They suffered deep shock as a result of their exposure to so much death and destruction, and they withdrew into themselves, feeling numbed, afraid, vulnerable, and very alone.

By collective trauma, I mean a blow to the tissues of social life that damages the bonds linking people together and impairs the prevailing sense of communality. The collective trauma works its way slowly and even insidiously into the awareness of those who suffer from it; thus it does not have the quality of suddenness usually associated with the word "trauma." It is, however, a form of shock—a gradual realization that the community no longer exists as a source of nurturance and that a part of the self has disappeared. "I" continue to exist, although damaged and maybe even permanently changed. "You" continue to exist, although distant and hard to relate to. But "we" no longer exist as a connected pair or as linked cells in a larger communal body.

The two traumas are closely related, of course, but they are distinct in the sense that either of them can take place in the absence of the other. For instance, a person who suffers deep psychic wounds as the result of an automobile accident, but who never loses contact with his community, can be said to suffer from individual trauma. A person whose feelings of well-being begin to wither because the surrounding community is stripped away and no longer offers a base of support (as is known to have happened in certain slum clearance projects) can be said to suffer from collective trauma. In most large-scale human disasters, of course, the two traumas occur jointly and are experienced as two halves of a continuous whole. For the purposes of this paper, however, it is worthwhile to insist on the distinction at least briefly, partly because it alerts us to look for the degree to which the psychic impairment observed in settings like Buffalo Creek can be attributed to loss of communality, and partly because it underscores the point that it is difficult for people to recover from the effects of individual trauma when the community on which they have depended remains fragmented.

I am proposing, then, that many of the traumatic symptoms experienced by the people of Buffalo Creek are as much a reaction to the shock of being separated from a meaningful community base as to the actual disaster itself.

It should be noted that "community" means much more in Buffalo Creek than it does in most other parts of the United States. Much has been said in the literature on Appalachia about the importance of kinship and neighborliness in mountain society. Although it is true that coal camps like the ones along Buffalo Creek differ in many ways from the typical Appalachian community, the people of Buffalo Creek were nonetheless joined together in the close and intimate bonds that sociologists call *gemeinschaft*. The rhythms of everyday life were largely set by the community in general and governed by long-standing traditions, and the social linkages by which people were connected were very strong. In Buffalo Creek, tightly knit communal groups were considered the natural order of things, the envelope in which people live.

Long stories must be made short in a presentation like this, so I will simply summarize my theme by stating that the human communities along Buffalo Creek were essentially destroyed by the disaster and its after-

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

math. The flood itself forced the residents of the hollow into a number of nearby refugee camps from which they were, for a variety of reasons, unable to escape. The result was that the majority of the Buffalo Creek survivors remained in the general vicinity of their old homes, working in familiar mines, traveling along familiar roads, trading in familiar stores, attending familiar schools, and sometimes worshipping in familiar churches. However, the people were scattered more or less at random throughout the vicinity—virtually stranded in the spots to which they had been washed by the flood—and this meant that old bonds of kinship and neighborhood, which had always depended on physical proximity, were effectively severed. People no longer related to one another in old and accustomed ways. The threads of the social fabric had snapped.

A year after the disaster (which is roughly when most of the authors represented in this section first encountered these people) visitors to Buffalo Creek were struck by a number of behavioral manifestations that seemed to be exhibited by almost everyone in the valley and, for that matter, continue to this day. Several of these manifestations are discussed elsewhere in this section. I would like to mention three by way of illustrating a larger point.

DEMORALIZATION

First, the survivors clearly suffer from a state of severe demoralization, both in the sense that they have lost much personal morale and in the sense that they have lost (or so they fear) most of their moral anchors.

The lack of morale is reflected in a profound apathy, a feeling that the world has more or less come to an end and that there are no longer any sound reasons for doing anything. People are drained of energy and conviction, not just because they are still stunned by the savagery of the flood but because activity of any kind seems to have lost much of its direction and purpose in the absence of a confirming community surround. They feel that the ground has been pulled out from under them, that the context in which they had worked, played, and cared for others has more or less disappeared. One survivor said,

> I don't know. I just got to the point where I just more or less don't care. I don't have no ambition to do the things I used to do. I used to try to keep things up. But anymore I just don't. It seems I just do enough to get by, to make it last one more day. It seems like I just lost everything at once, like the bottom just dropped out of everything.

I suppose the clinical term for this state of mind would be depression, but one can hardly escape the impression that it is, at least in part, a reaction to the ambiguities of postdisaster life in the valley. The survivors are literally out of place and uprooted. They had never realized the extent to which they relied on the rest of the community to reflect a sense of security and well-being, or how much they depended on others to supply them with a point of reference.

The people of Buffalo Creek are also haunted by a suspicion that moral standards are beginning to collapse all over the valley, and in some ways it would appear that they are right. As is so often the case, the forms of misbehavior people find cropping up in their midst are exactly those about which they are most sensitive. The use of alcohol, always a sensitive problem in Appalachian society, has apparently increased, and there are rumors everywhere that drugs have found their way into the valley. The theft rate has also gone up, and theft has always been viewed in the mountains as a sure index of social disorganization. The cruelest cut of all, however, is that younger people seem to be slipping away from parental control and are becoming involved in nameless delinquencies. This is an extremely disturbing development in a culture so devoted to the family and so concerned about generational continuity.

This apparent collapse of conventional morality has a number of curious aspects. For one thing, observers generally feel that there is much less deviation from community norms than the local people seem to fear. Moreover, there is an interesting incongruity in these reports of immorality—one gets the impression that virtually everyone is coming into contact now with persons of lower moral stature than they did formerly. This, of and by itself, does not make very much logistical sense. One survivor said flatly,

> The people of Buffalo Creek tended to group themselves together; therefore the breaking up of the old communities threw all kinds of different people together. At the risk of sounding superior, I feel we are living amidst people with lower moral values than us.

Perhaps this is true—but where did all these sordid people come from? Whatever else people may say about their new neighbors in the refugee camps, they are also from Buffalo Creek, and it is hard to avoid the suspicion that their perceived immorality has as much to do with their newness as with their actual behavior. It may be that relative strangers are almost by definition less "moral" than familiar neighbors. To live within a tightly knit community is to make allowances for behavior that might otherwise look deviant. New neighbors do not qualify for this clemency—not yet, at least—and to that extent, their very unfamiliarity may seem to hint at vice all by itself.

The collapse of morality in Buffalo Creek thus seems to have two edges. We have sufficient evidence to believe that certain forms of deviation are actually on the increase, although this is a difficult thing to measure accurately. However, we also have reason to believe that the breakdown of accustomed neighborhood patterns and the scattering of people into unfamiliar new groupings has increased the level of suspicion people feel toward one another.

DISORIENTATION

The people of Buffalo Creek are also clearly suffering from a prolonged sense of disorientation. It has often been noted that the survivors of a disaster are likely to be dazed and stunned, unable to locate themselves meaningfully in time and space. Time seems to stop for them; places and objects suddenly seem transitory. They have trouble finding stable points of reference in the surrounding terrain, both physical and human, to help fix their position and orient their behavior. All of this can be understood as a natural consequence of shock, but the people of Buffalo Creek seem to have continued to experience this sense of dislocation for months and even years after the crisis. "We find ourselves standing, not knowing exactly which way to go or where to turn," said one individual. Another survivor noted, "We feel like we're living in a strange and different place, even though it is just a few miles up Buffalo Creek from where we were."

Professional observers who have gone into the valley on medical or research errands have noted repeatedly how frequently the survivors seem to forget simple bits of everyday information—the names of close friends, their own telephone numbers, etc. People are often unable to locate themselves spatially, even when they are staring at fixed landmarks they have known all their lives. It is not at all uncommon for them to answer factual questions about time—their own age or their children's grade in school—as if history had indeed stopped on the date of the disaster. In general, people all over the valley live with a lasting sense of being out of place, disconnected, and torn loose from their moorings, and this feeling has far outlasted the initial trauma of the catastrophe itself.

People normally learn who they are and where they are by taking soundings from their fellows. As if employing a subtle form of radar, we probe other people in our immediate environment with looks, gestures, and words, hoping to learn something about ourselves from the signals we get in return. But when there are no reliable objects off of whom to bounce those exploratory probes, people have a hard time calculating where they stand in relation to the rest of the world. In a very real sense, they come to feel that they are not whole persons, not entirely human, because they do not know how to position themselves in a larger communal setting.

> Well, I just don't feel like the same person. I feel like I live in a different world. I don't have no home no more. I don't feel normal anymore. I mean, sometimes I just wonder if I'm a human being. I just feel like I don't have no friends in the world, nobody cares for me, nobody knows I even exist.

LOSS OF CONNECTION

A third manifestation of the disaster's psychosocial effects is a condition that might be described as loss of connection—a sense of separation from other people. For better or worse, the people of the hollow were deeply enmeshed in the tissues of their community; they drew their very being from them. When those tissues were stripped away by the disaster, people found themselves exposed and alone, suddenly dependent on their personal resources. The cruel fact is that many of the survivors proved to have few resources—not because they lacked the heart or the competence, but because they had spent so many years placing their abilities in the service of the larger community that they did not really know how to mobilize them for their own purposes.

Many people feel that they have lost meaningful connection with themselves. Much of their apparent former strength was actually the reflected strength of the community, and they are learning—to their very great discomfort—that they cannot maintain an enduring sense of self when separated from that larger tissue. They find that they are not very good at making individual decisions, getting along with others, or establishing themselves as separate persons in the absence of a supportive surround. "Lonesome" is a word many of them use, and they do not use it to mean the lack of human company. One woman who has moved to the center of a large neighboring town said of her new home: "It is like being all alone in the middle of a desert." A man who continued to live in his damaged home on Buffalo Creek said,

> Well, there is a difference in my condition. Like somebody being in a strange world with nobody around. You don't know nobody. You walk the floor or look for somebody you know to talk to, and you don't have nobody.

In addition, the inability of people to come to terms with their own individual isolation is counterpointed by an inability to relate to others on a one-to-one basis. Human relations along Buffalo Creek took their shape from the expectations that pressed in on them from all sides like a mold: they were regulated by the customs of the neighborhood, the ways of the community, and the traditions of the family. When that mold was stripped away, long-standing relationships seemed to disintegrate. This is true of everyday acquaintances, but it is doubly—and painfully—true of marriages. Wives and husbands discovered that they did not know how to nourish one another, make decisions, or even to engage in satisfactory conversations when the community was no longer there to provide a context and set a rhythm. There has been a sharp increase in the divorce rate, but that statistical index does not begin to express the difficulties the survivors have relating to their spouses. It is almost as if communal forces of one sort or another had knit family groups together by holding them in a kind of gravitational field, but when the forces of that field began to dissipate, family members became scattered like aimless individual particles. Each individual nurses his or her own hurts and tends to his or her own business. They

do not know how to care for one another or to coordinate emotionally, because the context that lent substance and meaning to their relationships has disappeared. Two survivors put it this way:

> Each person in the family is a loner now, a person alone. Each of us is fighting his own battles. We just don't seem to care for each other anymore.

> The family is not what they was. They're not the same people. I don't know how you'd put this, but before there was love in the home. But now it seems like each one is a different person, an individual by himself or herself, and there's just nothing there.

Finally, the difficulty people experience in sustaining warm relationships extends beyond marriages and families, out into the rest of the valley. In places like Buffalo Creek, relationships are part of the natural order—being inherited by birth or acquired by physical proximity—and the very idea of "making" friends or "forming" relationships is hard for these people to understand and harder still for them to achieve.

One result of all the problems I have described is that the community (what remains of it) seems to have lost its most significant quality—the power it gave people to care for one another in moments of need, to console one another in moments of distress, and to protect one another in moments of danger. In retrospect, it is apparent that the community was indeed stronger than the sum of its parts in this regard. When the people of Buffalo Creek were clustered together in the embrace of a community, they were capable of remarkable acts of generosity; when they tried to relate to one another as separate individuals, they found that they could no longer mobilize the energy to care. One woman summed it up in a phrase: "It seems like the caring part of our lives is gone."

CONCLUSIONS

To end with an oversimplified metaphor, I would suggest that the people of Buffalo Creek were accustomed to placing their individual energies and resources at the disposal of the larger collectivity—the communal store, as it were—and then drawing on those reserves when the demands of everyday life made this necessary. When the community more or less disappeared, as it did after the disaster, people found that they could not take advantage of the energies they once invested in that communal store. They found themselves almost empty of feeling, devoid of affection, and lacking all confidence and assurance. It is as if the cells had supplied raw energy to the whole body but did not have the means to convert that energy into usable personal resources once the body was no longer there to process it.

Children of Disaster: Clinical Observations at Buffalo Creek

BY C. JANET NEWMAN, M.D.

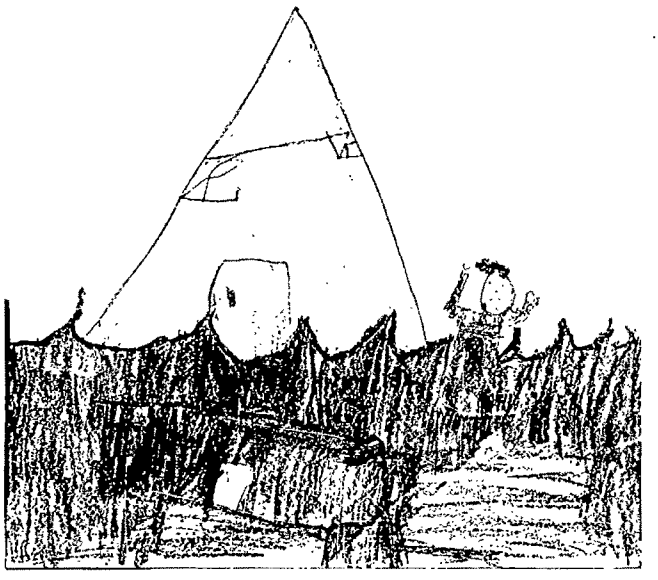
Most of the 224 children who were survivor-plaintiffs of the Buffalo Creek disaster were emotionally impaired by their experiences. The major factors contributing to this impairment were the child's developmental level at the time of the flood, his perceptions of the reactions of his family, and his direct exposures to the disaster. The author focuses on children under 12, describing their responses to fantasy-eliciting techniques and their observed behavior after the flood compared with developmental norms for their age and reports of their previous behavior. These children share a modified sense of reality, increased vulnerability to future stresses, altered senses of the power of the self, and early awareness of fragmentation and death. These factors could lead to "after-trauma" in later life if they cannot make the necessary adaptations and/or do not receive special help to deal with the traumas.

AS PART of the psychiatric evaluation of the survivors of the Buffalo Creek flood, 224 children were interviewed and evaluated; most were found to be significantly or severely emotionally impaired by their experiences during and after the flood. In this paper I will focus on children under the age of 12, using as a sample 11 of the children I assessed personally.

As has been described elsewhere in this section, the evaluation procedure began with an interview of the total family and proceeded to individual interviews. In interviews of mothers, outlines of each child's developmental history and functioning before and after the disaster were obtained. This information was passed on to the child psychiatrists in order to help us place each child in his parents' developmental perspective. Children were usually seen in their own rooms. They were encouraged to recall their own experiences of the flood; such expressions had often been submerged or inhibited amidst the outpourings of more vocal family members. The issues we discussed included past and present family life, personal feelings, school experiences, and the childrens' perceptions of future hopes, the nature of the disaster, and the meaning of the lawsuit.

We used such fantasy-eliciting techniques as "three wishes," "draw a person," and story telling. Preadolescent children were asked to draw a picture of the flood as they remembered it. Special educators from the Children's Psychiatric Center obtained school data to confirm or correct parental impressions of major losses of academic achievement that persisted long after the disaster.

The effects of the disaster on children can be attributed to three major factors: 1) their developmental level at the time of the disaster, 2) their perceptions of the family's reactions to the disaster, and 3) their direct exposures to the disaster. This paper illustrates each factor and examines their numerous interactions.



DEVELOPMENTAL LEVEL

The developmental factor will be illustrated by contrasting the clinical evidence gathered from 3 latency age children and 2 preschoolers. A depressed, hopeless, and guilt-ridden 11-year-old boy who had discovered human remains in his immediate environment after the flood drew a starkly realistic picture of a completely submerged trailer that contained two people screaming for help. A house above the trailer was half filled with water, and a panic-stricken figure tried to keep afloat amidst the waves and debris of the flood waters. Drawings by 2 younger children showed a possible symbolic meaning of mountains to Appalachian children, i.e., the provision of humanlike functions of cradling and life sustenance (this contrasts with Lifton and Olson's remarks about the "overall environment, including nature itself, as threatening and lethal" [1]). An 8-year-old boy with a chronic anxiety reaction drew the "house-mountain" depicted in figure 1 as life-saving compensation for his temporarily lost and helpless parents. The drawing represents a traumatic regression to a wishful merging of parental security into a house-mountain in a partially beneficent environment. A 7-year-old child also indicated security in nature in a picture of himself climbing a steep hill behind his mother and aunt. He drew a tree below him, saying, "This is a tree I can hang onto if I slide down." Nature offers support when human beings suddenly seem helpless. In Appalachia, the mountains represent not only slag heaps and flood threats but tangible, reassuring security.

Revised version of a paper presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Newman is Director, Day Hospital Elementary Unit, Children's Psychiatric Center, 3140 Harvey Ave., Cincinnati, Ohio 45229, and Associate Professor of Child Psychiatry, Department of Psychiatry, University of Cincinnati College of Medicine.

FIGURE 1
An 8-Year-Old's Drawing of a "House-Mountain"

*Note that the trailer is destroyed, while the safe "mountain" acquires door and windows.

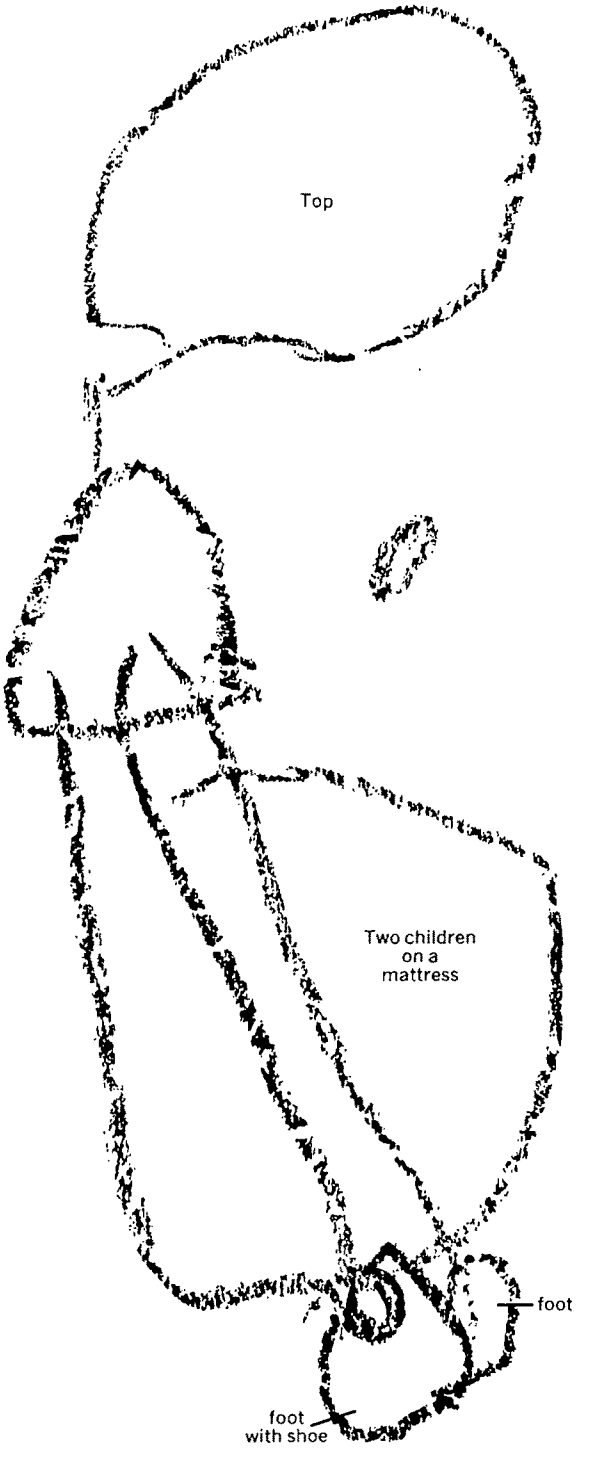
The experiences of 2 younger boys will be described to isolate developmental factors at the preschool level. Henry, who was 3 years old at the time of the disaster and 5 at the time of our interview, was the only son and favorite child of his mother's second marriage. He was the first to awaken on the morning of the flood. Looking out his window, he viewed the uncanny and perplexing sight of a house moving down the creek. Unsure whether this was real or a dream, he awakened his parents, conveying more cognitive bewilderment than fright or anxiety. He remembered saying, "Come and look!" The parents rose instantly and managed to evacuate the family to safety on high ground just in time.

Two years after the flood, his mother told us that Henry frequently slept in the same bed with her and loved to be rocked, although he had rarely needed this type of attention before the disaster. She reported that he often talked about the houses and cars that had floated by in the flood and how they "went boom!" I felt that because Henry was the first to awaken and, in a sense, rescued his family, they regarded him with special gratitude and admiration. During the family interview Henry was hyperactive—he was friendly but restless. In his individual interview, he recalled seeing the house going by his window and asking his parents to come and look. He denied being scared, but said, "I didn't like it." Henry also remembered seeing a screaming baby on top of an upside-down store that was floating downstream. He said, "I didn't like that either. I hated it."

Henry's flood picture started with a creek as an almost perfect circle. Then a curving line showed "how the creek goes here." A rounded object near the path of the flood conveyed its force; as he explained, "The flood threw this rock." Then Henry spontaneously drew a 3-sided rectangular but bottomless form nearby with "windows" for eyes, explaining that this was a person killed in the flood. Most children Henry's age, drawing their first human figures, use crude circles for heads or head-and-body combinations: in a precircle phase they use primitive scribble-strokes to indicate human figures. Henry had already manifested a capacity for drawing circles but had applied this skill only to his representation of the flood, using a bottomless rectangle with windows for eyes as a human figure. Such faces or human figures were interpreted as condensations of humans with buildings, stimulated by this 3-year-old's view of a peculiarly and perhaps awesomely floating house and other buildings, including the one the screaming baby was on. His flood experience started as he awakened from sleep, and sorting dream from waking perception and reality is typically difficult for young children. Developmentally, Henry was at a stage of tenuous differentiation of dream from reality and animate from inanimate objects, and motility is the first characteristic differentiating living from inanimate objects.

To summarize, Henry's drawing showed the human figure as dehumanized and fused with a seemingly animated building. The bottomlessness of the human face-figure suggests his lack of security, which was shown clinically by hyperactivity and an excessive need to be closer to his mother than he had been before. The circular flood moving huge rocks suggests the projection of superhuman powers to nature. His barely developed abilities to separate animate from inanimate and actuality from fantasy or dreams help to explain his current bewilderment, excessive anxiety, and hyperactivity. His favored position in the family and his role as "rescuer" have accentuated his sense of narcissistic omnipotence, which allays his underlying feelings of helplessness and anxiety. It is likely that his problems of immaturity, anxiety, and developmental deviations in cognition will become more evident when he starts school.

Peter was interviewed 2 years after the disaster, which occurred when he was 26 months old. His parents reported that he had been a happy baby, developing at normal rate. His father, a chronically disabled miner, described how the family scrambled up the side of the mountain behind their home and watched as their house was swept away and a nearby bridge crumbled from the force of the flood. A frantic passerby yelled to Peter's father to aid in the rescue of two children clinging to a floating mattress. As he ran to help, his wife screamed for him to come back. Realizing the danger, he ran back to his own children and led them to higher ground, carrying Peter on his chronically weak back.



Since the disaster, Peter cannot take a bath without screaming, and he still wets the bed frequently and screams in his sleep. He gets mad easily and always

wants his own way. Peter's memories of the flood involved concerns over the safety of his friends and an older brother's loss of his best friend. He referred to the "two kids on a mattress" and worried aloud whether "their daddy, he might just not want them." This must have represented his own fears at the hands of his own father, who did not save all children, limiting his efforts to the rescue of his own family. When asked about troubles or worries he said, perhaps stoically, "I don't be sad, that's all." When asked what would make him happy he said, "I don't know, maybe if my daddy was handy."

Peter's response to the three-wishes question was touching and highly original and was probably related to a 4-year-old's determination to hold on to reality, with a resulting fear of pretending, even for a moment: "I don't wish," he said proudly. His drawings, made at age 4, about his flood experience when he was 2 years old, should remind the reader of Henry, who, although he was perfectly capable of drawing good circles, drew a person as a house with a rectangular bottomless face. Peter, although younger, is involved with deeper, more sophisticated, more human views of the disaster.

Peter's first flood picture included irregularly round or oval outlines of what he then chose to call windows—an "ugly" window, a "shoe" window, and a "big" window. (Windows with views of the creek became highly important for many families.) As an afterthought, Peter drew a longer shape and told me to write "two kids on a mattress in the creek" within it. I then said, "Let's do that one again on a bigger page." Peter drew a mattress and started to draw the 2 children in the form of lines. However, in the process, he appeared to convert the children into 2 legs (one barefoot and one with a shoe)[1] and then drew a body and a head labeled "top," creating a total human figure. He was influenced by the fact that his siblings were drawing people. Figure 2 is Peter's second drawing: the writing is that of the interviewer during the process of drawing and records Peter's words. This is a powerful condensation of a traumatic scene, combining his father's failure to save all of the endangered children, particularly those on the mattress. These 2 children became the 2 legs of the larger total human figure in the picture. As with Henry, we see a variety of serious developmental interferences and emotional distortions in the development of perception and cognition as manifested in body image concepts.

A 4-Year-Old's Picture of Two Lost Children Condensed into a Primitive Human Figure

REACTIONS BASED ON DIRECT FLOOD EXPERIENCES

Marie was the cute, articulate daughter of a strong father and a dominating hypertensive mother; she was 8 years old at the time of the disaster. During the flood Marie's mother bundled her in blankets and carried her to shelter, never allowing the child to see the acute stages of the flood.

During Marie's interview, her "draw-a-person" pic-

[1]Many children were barefoot or half barefoot in the escape from the flood and suffered frostbite.

ture was of smiling, childlike parents in flowered clothing. Her flood picture, drawn from hearsay, seems traumatic at first glance. However, the bubbly clouds she drew were duplicates of the floral prints of the father's shirt and the mother's skirt in the draw-a-person picture. The houses stood high above the languid flood, and the many bodies appeared mostly in cheerful upright positions. Only 2 small figures yelled, "Help!" Marie exemplifies a child reacting to maternal anxieties, reminding us of the children described by Anna Freud and Dorothy Burlingham in *War and Children* (2), who reacted far more strongly to maternal emotions than to bombs.

The major clue to the anxieties underlying the facade of pollyannaish denial was Marie's response to the Despert Bird Fable, which elicits a child's story of what a baby bird who can fly a little will do if a strong wind blows the family nest from the tree, scattering the mother and father and baby bird. Marie asked, "Were they all close together or were they far apart?" I then said, "What do you think?" Marie replied,

> Mother makes another nest, with twigs, on a stronger branch. The little bird grows up to have a family. Or, maybe the mommy bird might get sick or die, or a cat might eat her. Or maybe the little bird might get sick or poisoned. It might mistake weed-killer for seed. That *could* happen. Oh well, the little bird probably got old and then died.

This story reveals a rapid descent from superficial health into violent and even paranoid ideation, involving the death of both mother and baby by violence and poison. This rapid weakening of defenses reveals Marie's vulnerability to and identification with a chronically anxious mother, whose exacerbated anxieties she had been intimately exposed to in the apparent service of being protected herself.

Richard, who was 7½ years old at the time of the disaster, was the middle child of 3, born to mature parents. On the day of the disaster, as soon as the water level fell, Richard and his father searched for relatives. They were concerned about the safety of Richard's older sister, who had stayed overnight with a girl friend. The sight of the mutilated body of a boy Richard's age was shocking to both the child and his father. Richard was described as a changed boy since the flood, having become tense, nervous, talking little to his parents, and suffering from terrifying nightmares of someone coming back from the black water to take him to the spirit world. When interviewed, he said that he usually slept with a blackjack under his pillow.

Richard's flood picture conveyed a firm sense of reality, a strong sense of form combined with creative sensibility. He drew a truck carrying 5 bodies wrapped in sheets, set against a background of a burning slag pile and a house with a large chunk missing. The sky was overcast and it was raining. His draw-a-person picture, a clever, strutting, colorful comic book character drawn in profile, shows color, movement, and detail and indicates creativity and ego strength. Despite enduring strengths in peer relationships, good school performance, and basically warm family ties, Richard has a chronic traumatic anxiety reaction manifested by trembling hands, tension, inner tremulousness, difficulty sleeping, and nightmares. In contrast to Marie, who looks deceptively healthy and self-assured but whose reawakened inner problems stem from close ambivalent ties to a chronically anxious mother, Richard's symptoms represent more purely a chronic overt traumatic reaction to the disaster, in the context of considerable ego strength.

David, 7 years old during the flood and 9 when interviewed, was apparently well-adjusted before the disaster. Afterward his grades fell, he tended to keep to himself, and got into fights. His most severe symptoms, however, were crying in his sleep, sleep-talking (saying he wants to "get home again"), and somnambulism—he seems to be walking *out* of the house. Although others direct him back to bed, he does not wake up during these episodes but appears frightened. Since the disaster he has been wetting his bed several times a night, something he did not do previously.

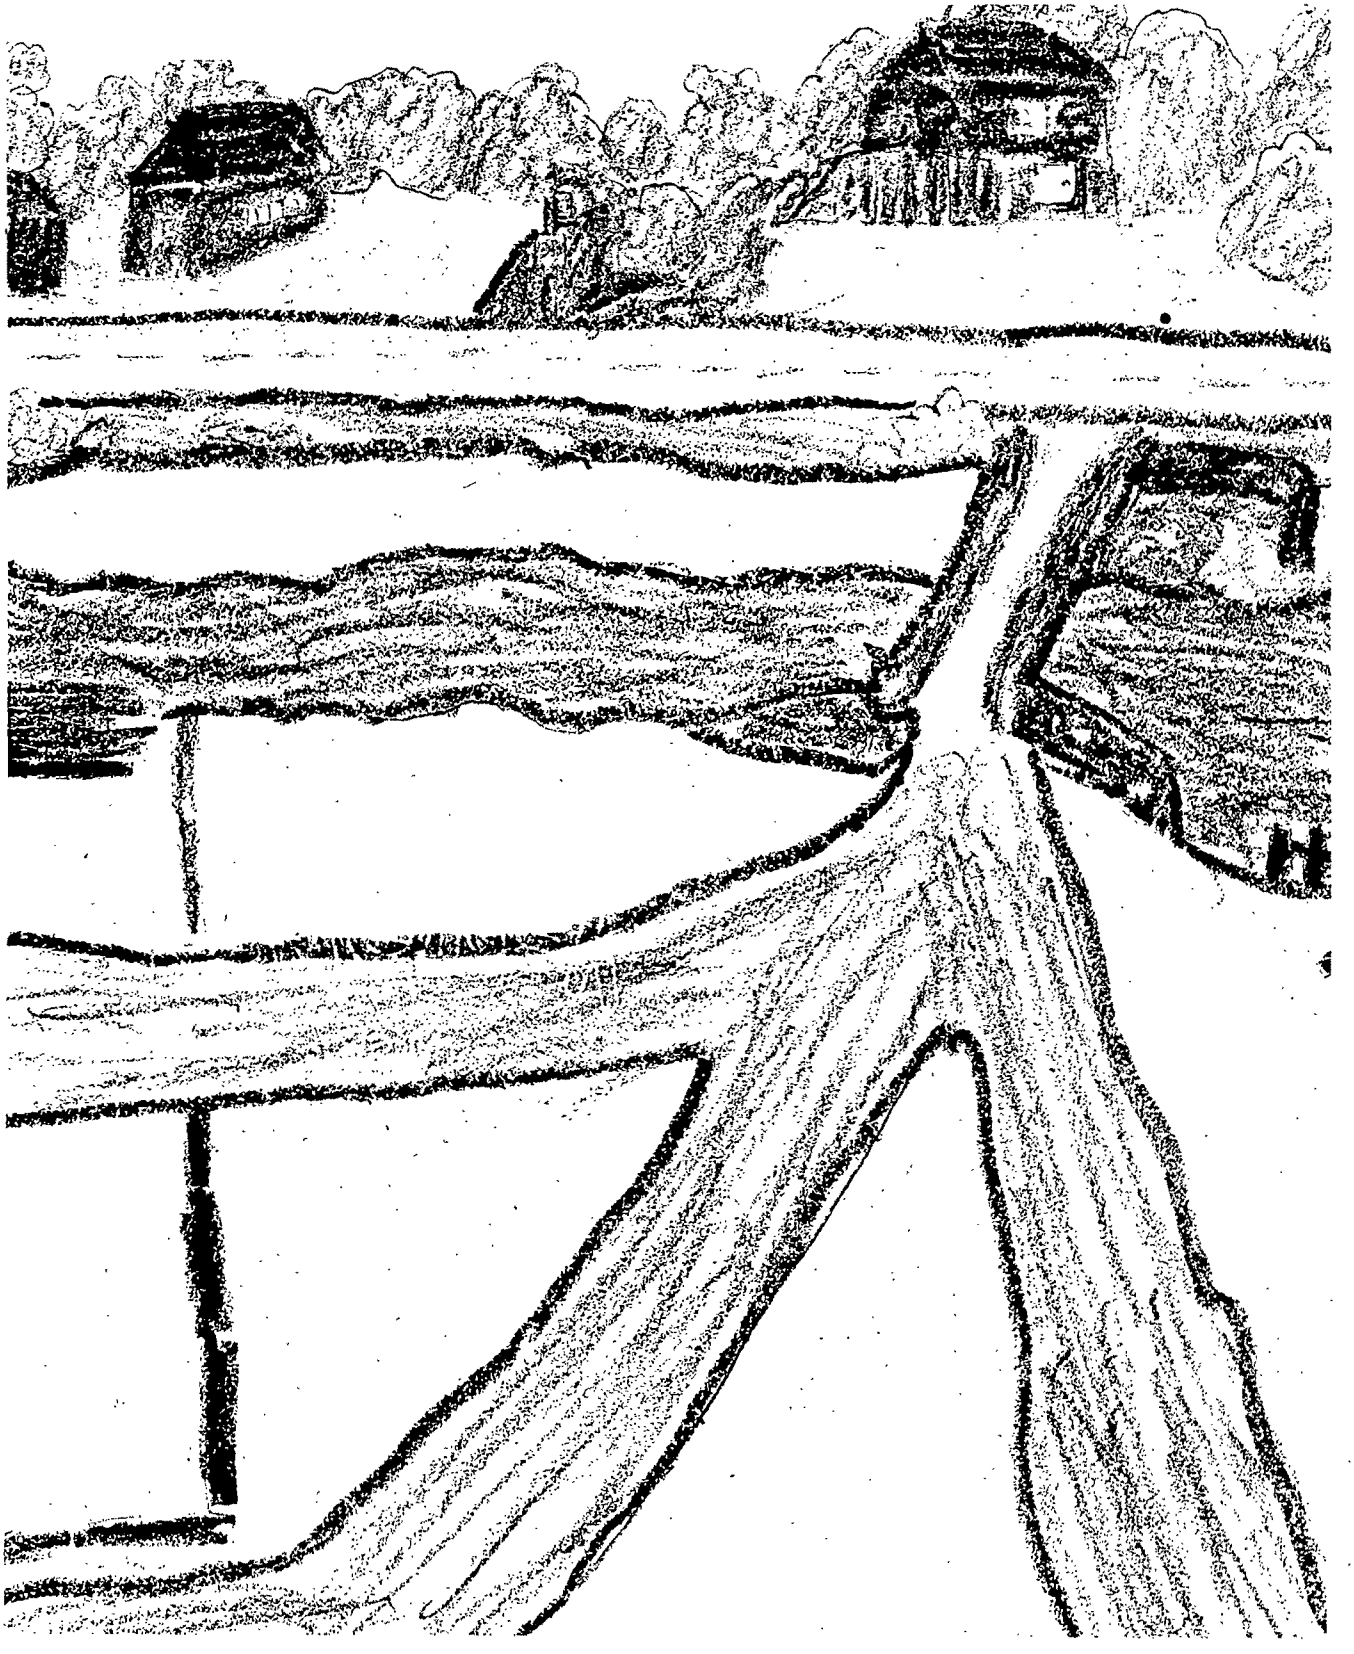
In his interview he appeared attractive and cooperative but quiet and somber. He did not recall the content of his sleepwalking episodes, although he vividly remembers people screaming while they were drowning during the flood. David drew a bizarre person with a strange colorless face looking backward and a brightly multicolored body with feet pointing in the opposite direction from the face (figure 3). Diagnostically, he had symptoms of a traumatic neurosis with a dissociative-type hysterical neurosis (exemplified by his somnambulism) encapsulated within it. It seemed likely that his trancelike sleepwalking was a repetition of the original escape; this interpretation was supported by his grotesque drawing of a person whose profile, while colorless, had a fixed smile and slightly quizzical or puzzled eyes. Facial distortions and poor fit to the body are evident in the picture.

David's pathology was focused and severe. Sleepwalking usually occurs in stage 4 sleep when central nervous system motoric inhibition of REM dreams cannot occur (3). Certain types are called "somnambulistic trances" and may represent physical reenactments or abreactions of traumatic situations (4). David's bizarre picture suggests an unconscious connection between his sleepwalking state and his conscious imagery.

Marie has become subtly but severely traumatized through her direct relationship with a chronically anxious and flood-traumatized mother, while Richard and David's more conspicuous and overt traumatic reactions stem more directly from their flood experiences. The contrasts in the symptom choices of Richard and David are probably multiply related to their constitutional backgrounds, developmental experiences preceding the trauma, and the exact circumstances of the moment of greatest trauma each experienced in the disaster.

FIGURE 3
A 9-Year-Old's Drawing That Suggests a Link Between His Somnambulism and Conscious Imagery

OBSERVATIONS ON OTHER AGE GROUPS



I have not mentioned another group of children, those who were in utero during the flood. Often, their preciousness lies in having survived the pregnancy of a frantic mother. Among their future stresses may be the never-ending tales or the silent allusions of the family about the disaster these children never experienced. The parents may see them as magically and profoundly linked with the flood. These children, as well as those born later (who will also feel left out, yet involved), will be unpredictably but importantly influenced by the catastrophe.

Although this paper has focused on preadolescent children, a few words must be said about adolescents' special vulnerabilities to the psychological effects of the disaster. Because the almost total community destruction, the loss of communality described elsewhere in this section by Dr. Kai Erikson, was so disruptive, especially to adolescents, they often had to choose between rebellious predelinquent behavior or compliant social withdrawal. They suffered deeply but privately when their parents broke down under stress. For example, in one family, the favored older brother, who had been the "good one" before the disaster, changed his behavior markedly—he missed 68 days of school, threatened the teaching staff, was suspended five times, and is currently on probation because of his behavior. At home he sat up at night apprehensively listening to rain or roared away on his motorcycle. However, his next younger brother continued to attend school regularly and made every effort to concentrate. The contrast between his very chaotic flood picture and a carefully drawn pink dove of peace that his teacher had praised as "best in the class" shows the range and conflict of his inner experiences, which he has internalized, but with unknown emotional strains.

Creative expressions emerged in many cases. Out of a highly disturbed large family living in two trailers in a state of chaos came a touching picture drawn by an 11-year-old boy (figure 4). Denying the turbulence of the flood, he drew an intellectually complex picture with excellent perspective that showed a trestle, road intersections, and a quiescent creek. He labeled one "the road to where we used to live." In the background, brightly colored idyllic homes in red, blue, and orange nestled among the woods on the hillside. There were no people in the picture, but there were possibilities for human reconstruction. The three dramatically split roads suggest important choices to be made, and the colorful homes in the background suggest hope.

Finally, some older children did follow the lawsuit and psychiatric interviews with great interest and sophistication. They recounted hopes of being lawyers and nurses, even though they were often having problems in their basic school courses. They wrote themes on safety regulations and dam construction as school projects and tried to master their experiences emotion-

FIGURE 4
A Hopeful, Creative Picture Drawn by an 11-Year-Old Child

ally and intellectually. They will never forget this experience, and they will be watchful of all the adults who have participated in it; they either idealize or are disillusioned with parents and other adults. When they grow up, they will watch the world closely. They will have learned enormously both in and out of school.

CONCLUSIONS

Children in traumatized families within a shattered community form their own theories of a disaster from their own reactions and their perceptions of the reactions of their parents and other adults. Their conceptions are also influenced by the social and legal processes associated with the disaster. All of these factors permanently affect their sense of self in growing up. The common heritage of most children of disaster is a modified sense of reality, increased vulnerability to future stresses, an altered sense of powers within the self, and a precocious awareness of fragmentation and death. In contrast to most of their parents, some of the children manifested clear and enduring evidence of hopefulness and creativity, despite obvious current limitations in their ability to achieve specific goals. Their sense of hope existed side-by-side with serious signs of developmental limitations and serious pathology. Indeed, the widening discrepancies between social sensitivities and academic achievement could lead to a severe "after-trauma" in later life. They would require unusual life adaptations or special help to respond constructively or creatively to the traumas they had undergone.

Discussion of the Buffalo Creek Disaster: The Course of Psychic Trauma

BY LEO RANGELL, M.D.

The specific contribution of the psychiatrist to the team study of the human disaster at Buffalo Creek focuses on the course of psychic trauma. The initial violent intrusion by the flood waters was followed by a second phase of the traumatic cycle, the physical dislocation of the survivors, with disruption of their "ground" and "surround." During this long subsequent period the level of trauma did not recede but kept rising, although at a slower pace. Distant effects of the trauma may succeed the more immediate ones. The finite psychic space of the survivors is encroached upon by traumatic memories for an indefinite period of time, leaving fewer resources available for normal effective living. The absorption and merging of traumatic stimuli into a traumatophilia poses still another potential problem. The unprecedented legal decision as to the linear effects of psychic trauma on a succession of connected individuals will need further interdisciplinary clarification.

IN OFFERING OPINIONS on the overwhelming human experience of the Buffalo Creek disaster, the challenge is to separate our reactions of empathy and horror (which, as Lifton and Olson [1] have pointed out, were quickly and painfully shared by all mental health professionals who came to the valley after the disaster) from the potential contributions of our specific professional expertise. Toward this end, I will focus on the realm of psychic trauma (2), its nature and its effects, to complement the findings of the interdisciplinary team of sociologists, psychologists, attorneys, and others who took part in the evaluation of the effects of this experience on those who survived it.

The articles in this section range from the individual to the collective, from the child to the adult, and from the deepest inner effects to the widest outer consequences of this sudden, unassimilable disruption of man's relationship to his physical world. These studies address not only the inundation of psychic structures in a horizontal sense but also the longitudinal effects of the flood—the disturbed continuity with the past, the shattering of the present, and the inescapable portents for the future.

The work of the interdisciplinary evaluation team retained by the law firm representing the 625 survivor-plaintiffs to assess the psychological impact of this catastrophe has profound implications, reflected in its effects on the social decision-making process. The unprecedented legal decision, reported elsewhere in this section by Mr. Gerald Stern, permitted people who were not on the scene of an accident to be awarded reparations for the psychic damages they suffered. The principle acknowledged in this case could well shake all existing rules of the social order about the responsibility of man to man.

THE FIRST PHASE: PSYCHIC NUMBNESS

To turn to the central focus about which psychiatrists can reflect and from which other observations will stem, the Buffalo Creek flood was a violent intrusion into the peaceful psychic life of the community massively beyond the "average expectable environment" (3). This eventuality was not, however, completely unexpected—the people in the valley had long lived with this possibility and knew it could be prevented, but they said they had put it out of their minds. Actually, it had been put not out but deeply in, had become part of their living unconscious. It was in some ways like the earthquake situation in California but worse and more constant. The dam that finally broke physically existed just above the valley and was visible and ever present. Another difference, which added the makings of a latent inner eruption to the potential external occurrences, was that there were in the minds of valley residents people (the owners of the dam) who could and should have done something about the situation. Like the cave-in of a coal mine in a community that has always lived in dread of such an occurrence, the flood had been part of the mental as well as the physical geography of Buffalo Creek, a feared event buried in the minds of the people. The massive convulsion of the physical world that took place on February 26, 1972, was a mental imprint come true. It was a nightmare from which this time they did not awake.

The black waters that roared through Buffalo Creek

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Rangell is Clinical Professor of Psychiatry, University of California, Los Angeles, School of Medicine, and immediate Past President of the International Psychoanalytic Association. Address reprint requests to Dr. Rangell at 456 North Carmelina Ave., Los Angeles, Calif. 90049.

valley when the fantasied, feared, and repressed event became reality could be said to have flooded the egos of those who lived through the disaster. All control functions were overrun by the sudden influx; it was a maximum dosage per unit time, a psychological overkill. The result was universal and with a common base to all, the traumatic state, the condition of psychic helplessness that the anxiety signal presages and that all of the ego's defenses constantly work to prevent (4, 5). This was the phase of psychic numbness observed in all of the studies of the survivors. The goal was merely to live through it, to survive. Each individual held on to whoever or whatever was left. "Psychological conservatism," which Drs. Titchener and Kapp describe in "Family and Character Change at Buffalo Creek," served to reduce excitation; no further stimuli were wanted.

This stage of psychic numbness, of apathy, withdrawal, and sluggishness, was still visible when the evaluation teams arrived in Buffalo Creek 2 years later. Some of the observers were surprised that the traumatic neurosis was still visible, but what evidence is there to assume that the residual or even basic effects of so massive a trauma would not last a lifetime? Psychological testing of survivors of the Nazi holocaust has shown that after 30 years they still show such lasting effects as impairment in perceptual-cognitive functioning, withdrawal from objects, inability to sustain close relationships, and other subtle and overt sequelae.

While the legal experts perhaps needed to be concerned about the claim of preexisting states, I would prefer to maintain clarity and not to have to use the word "impairment," to blur the fact that there *was* loss, injury, and illness. The effects of the disaster were as ravaging as an epidemic of typhus or plague, which is similarly visited upon a city from without, and the preexisting vulnerabilities in the hosts to receive the invading organisms are not an issue. The traumatic neuroses overshadowed psychoneuroses. I do not mean to say that there were no preexisting psychoneuroses, but rather that they no longer had a chance to assert themselves. This is an issue that has plagued every psychiatrist who has served in the military. Combat neuroses in their acute phases are more uniform than different in their presenting syndromes; only later can individual differences reappear and assert themselves again. During the years to come, as normalcy returns to the Buffalo Creek survivors, they will have the luxury of becoming individually neurotic again.

THE SECOND PHASE: "GROUND" AND "SURROUND"

What happened to this community in terms of incoming traumatic stimuli did not stop with the cataclysmic events of that Saturday morning. As disorienting and time-stopping as the flood was, it was only the first phase. An individual who suffers a loss, however shattering, generally returns to his home to start the long and difficult process of repair. His "ground," the background into which the self can merge, is the base for his security, the source of the nurturing supplies that sustain the processes of reparation. This was not possible in Buffalo Creek. The dazed survivors were returned not to their familiar ground but to new and strange surroundings. This may have been the only possible course, but it was still depriving and further threatening. Rather than nurturance, the survivors continued to face challenges, for a long time and during a raw and vulnerable state.

In this double and almost death-dealing blow, these survivors repeated the experiences of other holocausts known to our generation. Those who survived and escaped from Nazi Germany wandered into new lands. The survivors of the atom bomb returned to craters where their homes had been. Many South Asians have had to leave their land after having left their dead. In all of these cases, the survivors' earth is also gone after their fellow humans have disappeared.

Years ago, writing at another level and about more comfortable aspects of human troubles, I described "attachment to ground" as the psychic prerequisite for the maintenance of the social state of poise (6, 7). The opposite condition, a wavering hold on one's surrounding psychic ground, results in a basic anxiety with the threat of crumbling and even annihilation of the self. This is the source of the primitive anxiety that people feel at the first threatening tremor of an earthquake. In the more mundane case of seasickness, the fear has been said to be not that one will die, but that one might not. Underlying both of these disturbing states is an elemental anxiety that stems from a disorientation in the relationship of the organism to the earth under its feet.

In the course of ontogenetic development, this relationship extends from the ground beneath one to the space around him, to people, institutions, atmosphere, and the culture. This is the common background in the phenomena described by Freud in the oral stage (8), in the attachment studies of Bowlby (9), in Mahler's contributions on separation-individuation (10), the effects of motherlessness on the primates studied by Harlow (11), and in the natural experiments on human infants studied and documented by Spitz in cases of marasmus resulting from early and massive deprivation (12).

Not only did the ground of the Buffalo Creek valley literally sink beneath the feet of its inhabitants, initiating the most primeval regression man can experience, but when the survivors reached solid high ground, they were again deposited on an insecure terrain, into a social "envelope,"—an intriguing term used by Dr. Kai Erikson—of unfamiliar space. The trauma thus did not end, it merely changed. There are strain traumata (13), shock traumata (14), cumulative traumata (15), and sudden overwhelming disruptive events. The stimulus barrier can be bent as well as rent (16). At this point, the trauma of the survivors changed from

sudden to cumulative. The flood receded, but the level of trauma did not; rather, it kept rising, although at a slower pace.

This was the phase studied intensively by Dr. Kai Erikson, described in this section from the sociological standpoint as a loss of communality, the social tissue that binds people together. While this loss was universal, we should not overlook the fact that it was an individual trauma as well. Just as the original traumatic state, although universally shared, was individual in suffering, so was it with this second phase of the traumatic cycle. The change from the familiar to a strange surround during the period when rest and nurture were needed superseded the initial trauma and prolonged and compounded its effects in each survivor.

THE THIRD PHASE: FUTURE EFFECTS OF THE TRAUMA

The articles presented in this section survey the effects of the disaster to date. Less measurable are the future effects, especially those which are more subtle and internal. Are the children Dr. Newman interviewed who are now getting along well in school less vulnerable to future stresses than those who are currently more turbulent and disturbed? Or is the reverse the case? Only long-term longitudinal studies (which are not likely to be practical or feasible) would answer this and similar questions.

There are subtle and far-reaching issues facing the survivors. In spite of the vastness of the unconscious, psychic space is limited. There is room and time in any individual psyche for only a limited amount of cognitive ideation and a finite number of memories, fantasies, and accompanying affects. The product of such space and time comprises the psychic life of an individual, the amount already spent and the amount still left. Mourning is a model of such an occupation of psychic space, a paradigm of how obsessive thoughts and memories related to psychic work that needs to be done crowd and consume the psychic capacity. Traumatic memories of any kind encroach on this psychic time-space and reduce its available quantity; this is why psychic traumata age people.

I have been treating a woman in her mid-seventies and have discovered that her apparent senility is due not to an organic aging process but to the repression of decades of a traumatic life. She had told herself—she brought this out with clarity through her foggy memory in sessions that had a hypnotic quality—that she did not want to remember any part of her married life of close to 50 years. The volume and intensity of the traumatic memories being repressed left her almost no room for normal living. She had by now assumed the posture, both mentally and physically, of a diffuse cortical atrophy, without evidence, either neurological or radiological, of any organic syndrome nor even convincingly of cerebrovascular disease. She was like a young, acute, traumatic amnesia, except that this was chronic, old, and massive. Her mental state undulated dramatically with the emergence and rerepression of forbidden thoughts. This poignant clinical experience has made me wonder about the general psychopathology of "old age."

How much space will the Buffalo Creek experience occupy in the minds of the survivors in their future lives? We routinely treat patients who react to a deprived childhood by sacrificing a certain percentage of their psychic lives. I have treated a patient who has occupied perhaps a quarter or a third of her free associations with obsessive preoccupation over her screaming mother; her thoughts are similarly occupied outside of the analysis. Another of my patients has been unable to enjoy his current life because of the constant crowding of his psychic space by the coalesced memories of the threats of castration that pervaded his tortured childhood. I have pointed out elsewhere (17) the role of such chronic traumata in producing the cacophony of human relationships in ordinary life.

These situations represent fairly common developmental traumata. How much more of a role do cataclysmic traumata like the Buffalo Creek disaster play? What will be the long-term effects of the vivid, massive "death imprint" described by Lifton and Olson (1)? What will be the effects on children in whom death anxiety has been violently added to the normal anxieties of separation and castration? It seems likely to me that their memories will repeat the accumulated traumata over time like a long-acting timed-release capsule.

There was an element in this disaster that is not present in truly natural catastrophic events, which serves to explain further why the "Buffalo Creek syndrome" is not limited to reactions to external events, but rather reflects added internal idiosyncratic forces. I am referring to the human element, the thought and the accusation that this horrible occurrence could have been prevented. Unlike a natural disaster such as a tornado, where inanimate forces of nature are solely responsible, the human object was involved in the Buffalo Creek Flood, which arouses impulses of aggression and retaliation. Channels for discharging these impulses do not keep pace with the amount and quality of the impulses aroused. The ego is bombarded from two directions, and feelings of rage, impotence, anxiety, guilt, and depression are added to the usual responses to disaster.

The more external normalcy returns, the more will traumatic neuroses and psychoneuroses be in a reciprocal relationship to each other. The residual trauma will stimulate individual neuroses, and latent neuroses will feed upon and perpetuate the traumatic state. Such restitutional movements are already evident in the survivors and will increase with passing time. Phobias, obsessions and depressions, and private anxieties and conflicts have already been noted by various observers, and survivors' dreams are beginning to reveal their predisaster concerns.

There are other more subtle unknowns to cloud the future. What happens when a traumatic effect merges

over time into a traumatophilia? Such an outcome can represent a repetition compulsion not in the service of mastery but to satisfy a sense of guilt or a need for punishment, a trauma that is absorbed and utilized by the psychic forces "beyond the pleasure principle" (18). Or what will be the result when the pleasure formulae or safety mechanisims themselves become altered and individually fashioned as a result of the traumatic experience? I am reminded of a patient who was traumatically raped and now finds her husband and all other men to whom she turns passive and weak. Or a patient who, from a traumatic rejection in her first love, has come to no longer believe in love. Another patient, similarly hurt, now feels "I'll never again have a best friend." What will be the effects of the life-threatening insult at Buffalo Creek, seen by the survivors as a result of neglect by people in authority, on trust, love, and object relations? One can hardly begin to tell, but one can be prepared so as not to be surprised.

In surveying this event and the reports that have been presented in this section, we should not overlook the effects of the studies themselves on the 625 survivor-plaintiffs evaluated. Aside from the legal result, the interest displayed by caring individuals from the society outside the valley probably introduced a therapeutic influence, however circumscribed. This influence might be compared to the effects on a therapeutic ward of the mere announcement of a program of treatment. However, there may also be negative effects: divisiveness has been introduced in the valley. Just as the untreated "control ward" suffers by comparison with the therapeutic community, those survivors who were not among the litigants may feel left out and discriminated against.

While an important and unprecedented legal decision has been achieved that greatly extends the definition of psychic trauma following an external event, the full implications of the human phenomenon described in this section cannot be estimated. Anyone who is lost, hurt, or otherwise affected under traumatic circumstances affects others in an endless chain that is attenuated only by emotional distance. It would be illusory to believe that it is within our power or professional expertise to accurately describe ethical guidelines for the rectification of the linear progress of traumatic effects. I recently knew of an elderly couple who were being displaced from their home for the building of a federal project. During the process, the husband, distraught over the dislocation, suffered a fatal heart attack. What can we say or what should we do about the effects on his wife? Or the children? Or a chain of others? There are more questions than we can answer. We must work side by side with the law, with sociology, philosophy, and all thinking and feeling people. No one or no group has a corner on ethics or on wisdom.

Carbon Monoxide Encephalopathy: Need for Appropriate Treatment

BY ROY GINSBURG, M.D., AND JOHN ROMANO, M.D.

The authors describe severe psychiatric and neurological sequelae in a patient who suffered carbon monoxide poisoning as a result of a suicide attempt. A review of the literature revealed that 15 to 40% of survivors of carbon monoxide poisoning develop neuropsychiatric symptoms, often following a period of apparent recovery. The authors advocate an aggressive treatment approach to carbon monoxide poisoning, emphasize the diagnostic value of extensive laboratory testing, and suggest that 2 to 4 weeks of bedrest may prevent delayed neuropsychiatric sequelae.

RECENT OBSERVATION of a patient with carbon monoxide poisoning drew our attention to the great variety of neurological and psychiatric symptoms in this disorder and to the lack of clarity concerning its clinical course and treatment. This paper describes the clinical course of a patient with carbon monoxide encephalopathy, reviews some of the major findings from the literature, and suggests some new approaches to treatment.

CASE REPORT

The patient, a 59-year-old housewife of Italian extraction, became depressed in June of 1973 and tried to commit suicide by car exhaust inhalation. A neighbor who was a registered nurse investigated within an hour and found the patient cyanotic and unresponsive. She was taken to the nearest hospital emergency room, where she was stuporous but not comatose, and was not "cherry red." Neurological examination was unremarkable, and a carboxyhemoglobin level was not obtained. An EEG and brain scan were within normal limits. There was no history of neurological or psychiatric illness.

After admission the patient became more alert but appeared depressed and could not concentrate. She was given three electroconvulsive treatments within a week. At first the patient seemed less depressed, but then she became increasingly confused and withdrawn, refused to eat, and developed stereotyped picking movements. Three more ECT treatments were given 3 weeks after admission, but the patient's confusion increased. Because of the unclear nature of her illness, she was transferred to Strong Memorial Hospital for further evaluation.

A physical examination on admission revealed a mute, uncooperative patient with intermittent posturing. She responded with body movements to some commands but would not open her eyes or talk. The only positive physical or neurological finding was a bizarre gait; the patient would stand in place and make small shuffling movements with her feet while moving her body in a clockwise rotation.

Laboratory tests revealed that the patient's hematocrit was 35% and the hemoglobin revealed beta-thalassemia. Electrolyte levels, calcium, phosphorous, blood urea nitrogen, serum glutamic oxalacetic transaminase, lactic dehydrogenase, alkaline phosphatase, creatinine, total protein, albumin, glucose, uric acid, urinalysis, serology for syphilis, T-4 by Murphy Pattee, brain scan, and skull X-rays were all within normal limits. A lumbar puncture revealed normal opening and closing pressures and no cells; cerebrospinal fluid protein and glucose levels were within normal limits. Electroencephalogram on admission and repeated five times since to the present revealed persistent symmetrical monorhythmic three-cycle per second activity which was only present during drowsiness.

The patient spent most of her 4 months in the hospital on the floor, sitting, rocking, and staring blankly. She occasionally responded by giving her name in a faint whisper but otherwise would not talk to the nurses or her physicians. She often defecated in bed, and was sometimes physically aggres-

When this work was done the authors were with the Department of Psychiatry, Strong Memorial Hospital, University of Rochester School of Medicine and Dentistry, Rochester, N.Y., where Dr. Ginsburg was Associate Resident and U.S. Public Health Service Fellow in Psychiatry, and Dr. Romano is currently Distinguished University Professor of Psychiatry. Dr. Ginsburg is now a Grant Foundation Fellow in Psychopharmacology, Department of Psychiatry and Behavioral Science, Stanford University, Palo Alto, Calif. Address reprint requests to Dr. Romano at the Department of Psychiatry, University of Rochester, Rochester, N.Y. 14620.

The authors would like to thank Drs. Robert Joynt, Lowell Lapham, and John Strauss for reviewing the manuscript.

sive. An interview with intravenous sodium amytal revealed that the patient was oriented for time, place, and person, and that she could talk about her depression and of her bizarre behavior as being like "something out of a book." After the first amytal interview, the patient was able to talk to the nursing staff, dress herself, and come to the dining room to eat. However, by the next morning she was again mute and lying in bed. For a period of 3 months the patient was given frequent amytal interviews and these were, with some exceptions, the only times she would talk. Treatment with trifluoperazine and then chlorpromazine in high doses was tried without effect and then discontinued.

After 4 months without improvement, the patient was transferred to the Rochester Psychiatric Center for long-term care. Since then the patient's clinical course has not changed significantly. She has generally remained mute, but when she does speak she confabulates. It became clear to the staff that she had considerable difficulty remembering recent events. Repeated neurological examination revealed bilateral tendon hyperreflexia, mask-like facies, and a parkinsonian gait.

LITERATURE REVIEW

The toxic effects of carbon monoxide (CO) have been known for centuries. In the past, household gas containing CO was the principal source of both accidental and suicidal ingestion. With the increasing use of natural gas and electrical heating this type of exposure has diminished. However, the development of the gasoline-burning internal combustion engine, which produces exhaust gases containing between 5 and 9% CO, stimulated an increased use of this gas as a suicidal agent (1).

The incidence of nervous and mental sequelae following CO poisoning was first reported to be 0.8% in 1936 (2). More recent reports describe a remarkable increase in the incidence of aftereffects to between 10–30% (3–6). Between 60 and 75% of patients with carbon monoxide poisoning survive the initial trauma, and 15–40% of those who survive have neuropsychiatric sequelae (4–6). Approximately 10–30% of patients develop neuropsychiatric signs 1 to 3 weeks after exposure (2, 6).

CO acts by displacing oxygen from the hemoglobin molecule and shifting the oxygen-hemoglobin dissociation curve to the left, thus increasing the binding of oxygen and hemoglobin. It displaces oxygen because the affinity of hemoglobin is 200 to 290 times greater for CO than for oxygen. A small quantity of CO can reversibly inactivate a substantial percentage of the oxygen-carrying capacity of the blood. The significance of a small amount of carboxyhemoglobin concentration is seen in the tremendous reduction this has on arterial oxygen tension (P_{O2}). For example, a carboxyhemoglobin concentration of 9% may be equivalent to a 30% reduction of hemoglobin or a 46% reduction of arterial P_{O2} (7). This shift substantially decreases the oxygen tension supply to the tissues (8).

The development of neurological signs has not been correlated, either clinically (1, 6, 9) or in experimental work (10), with the amount and length of exposure to carbon monoxide or the carboxyhemoglobin level. However, there may be a gross correlation between the patient's level of responsiveness on admission to the hospital and development of neuropsychiatric sequelae (4, 5). The half-time of excretion for low concentrations is from 2 to 4 hours (8); higher concentrations may take 7 to 10 days to be completely eliminated (11). CO in concentrations as low as 50 parts per million can produce notable effects on mentation (8). The inhalation of a 1% concentration is usually fatal to a resting man in 30 to 40 minutes and to a working man in 10 minutes. A concentration of 0.01% produces light headache and 0.2% produces coma. Children, who have a higher respiratory rate, die more rapidly than adults (9).

The entire range of focal and general neurological and psychiatric syndromes has been reproduced by carbon monoxide (2, 5, 6, 9, 12–17). The "cherry red" color traditionally associated with CO poisoning is actually uncommon; in one series it was found in only 6% of patients (3). Patients presenting in the emergency room will often have nausea and, depending on the degree of cardiovascular competence, may also have hypotension, metabolic acidosis, and angina pectoris (18). The first neurological symptom to appear is frontal headache (19). The headache is often a delayed phenomenon; thus, lethal concentrations of CO may not produce any warning symptoms. Prompt administration of oxygen before the headache becomes intense usually abolishes the pain (19).

Often the fluctuating symptoms from CO mimic those of psychotic depression or of hysteria (5, 6, 12, 20). In particular the rapid changing of apraxias, agnosias, astasia-abasia, and the amnestic-confabulatory state often contributes to a false diagnosis of hysteria. It is also reasonable to assume that "hysterical" defense mechanisms may be used by patients who realize that they are damaged. Weinstein and Kahn (21) have described many patients with severe illness who used rather bizarre denial mechanisms rather than face the overwhelming task of confronting their disability.

Recovery rates of those patients who do not relapse vary from several days to as long as 8 months (5). As would be expected, the highest cerebral functions recover last.

Delayed neurological reactions after carbon monoxide poisoning have been of increasing concern. Patients often have negative neurological and psychiatric examinations within several days after their original exposure and are either discharged from the hospital or allow to become ambulatory. Plum and associates (20) stated that "anoxia is usually severe; most patients are in deep coma when found but awaken within 24 hours. Nearly all patients resume full activities in 4 or 5 days." The patient usually does well for between 2 to 21 days and then can develop the whole spectrum of neuropsychiatric signs and symptoms. Deterioration may either progress to coma or death or be-

come arrested at any point. Some patients have a second recovery period which can lead to full health (20). There is no way to distinguish those patients who will recover from those who will relapse.

Laboratory tests can be of some value in cases of CO poisoning. Initial screening for toxic agents can rule out the presence of central nervous system depressants, which have been found in as many as 20% of CO ingestions (3). Electrocardiograms can reveal inverted T-waves and ST wave depression (6, 8). Cerebrospinal fluid pressure may occasionally be elevated or a few lymphocytes may be seen (22). Pneumoencephalogram (in patients with marked damage) shows enlarged ventricles and cortical atrophy. Over 90% of patients have electroencephalogram abnormalities, consisting of slow waves (2 to 5 cycles per second) of low voltage, frequently with a frontal preponderance (10, 23–26). In general, the severer the EEG changes, the severer are the sequelae. Patients with frontal dominance most often show general and focal neurological signs and dementia. Improvements in EEG findings parallel the patient's clinical condition (26). Sleep EEGs may predict improvement; patients who have the most REM sleep usually have the best clinical course (27).

The pathological effects of CO poisoning are present in almost all organs of patients who die from acute intoxication. However, the most important changes occur in the brain, where edema, capillary and venous dilatation, and hemorrhagic necrosis are acute (6, 9, 20, 28). These lesions are similar to those resulting from cardiac or respiratory arrest, hypoglycemia, or cyanide poisoning (5, 11).

Later pathological changes include demyelination of the white matter (anoxic leucoencephalopathy) in contrast to the usual predominance of lesions in the gray matter during the early stages (6, 9). The demyelination is often speckled and gives a "moth-eaten" appearance. The gray matter regions of the brain most commonly involved are Ammon's Horn; the part of the cortex situated below the cerebral sulci, particularly levels II, III, and IV; the pallidum; the thalamus; and the Purkinje cells of the cerebellar cortex. This predictable distribution of anoxic lesions is not consistent with the tremendously varied and unpredictable clinical constellation.

Three factors have been persistently identified in the production of anoxic lesions from carbon monoxide: hypoxidosis, edema, and circulatory disorders (10, 28, 29). The edema is thought to occur as a result of anoxic lesions to the vascular wall, and it brings about not only changes in the nerve and glial cells but also intracranial hypertension and compression of various vessels. Circulatory disorders are thought to arise from hypotension because of decreased output from the left ventricle (10), increased venous pressure with poor venous drainage because of right ventricular malfunction (29), and possible obstruction of small blood vessels by swelling of the endothelium or vasospasm (30). The need of white matter for oxygen is five times less than that of gray matter and therefore it is remarkable that the white matter may show the more extensive lesions (30). This has been explained by the hypothesis that white matter may be more susceptible to anoxia and edema because of a less redundant arterial supply. Lesions may occur more frequently in the subcortical white matter because there are fewer small vessel anastomoses than in deeper cerebral white matter (10). The size of the white matter lesions and the neurological signs have been correlated in experiments with the degree of metabolic acidosis and systolic hypertension but not with the extent of hypoxia (10).

CASE DISCUSSION AND TREATMENT RECOMMENDATIONS

Our patient presented a very confusing clinical picture. Although carbon monoxide poisoning remained the primary diagnosis, hysterical psychosis, schizophrenia, and psychotic depression were also considered as possible diagnoses. The diagnosis was difficult because of the patient's bizarre behavior, the wide and frequent clinical fluctuations, and her apparent lack of dementia under amytal sedation. However, the course of severe dementia over several years, the amnestic-confabulatory state, mutism, parkinsonian facies and gait, hyperreflexia, and the slowing on the EEG have implicated carbon monoxide poisoning as the diagnosis.

We suspect that some realization of her damaged state led the patient to increase her bizarre behavior to assure herself that she still had some control over her actions. This bizarre behavior, which disappeared during amytal interviews, is consistent with both the hysterical and denying defense mechanisms discussed by Weinstein and Kahn (21). Consequently, amytal interviews, which eliminated the hysterical aspects, were not helpful in diagnosis.

A severe depression led to our patient's carbon monoxide ingestion. Her hematocrit of 35% secondary to beta-thalassemia may have added to her susceptibility to CO. She initially improved, and was given six ECT treatments for depression. We cannot predict what her subsequent course would have been without ECT, but the increased metabolic demands of convulsive activity on the central nervous system may be related to the delayed onset of anoxic leucoencephalopathy (20, 28, 31).

Because many physicians are unfamiliar with this disorder, patients with carbon monoxide poisoning are often not treated as the data above indicate they should be. We recommend the following regimen:

1. When the patient is first seen, blood should be drawn for a carboxyhemoglobin level. Although the carboxyhemoglobin level does not correlate consistently with eventual neuropsychiatric deficits, it is useful as a guide to determine the extent of exposure because clearing is relatively slow.

2. Because of the high incidence of associated intake

of other drugs, blood and urine should be studied to determine if central nervous system depressants are present.

3. Since acidosis frequently accompanies carbon monoxide poisoning, arterial blood gases should be determined. The metabolic state of the central nervous system lags several hours behind that of the circulatory system; thus, acidosis that is not severe in the peripheral vascular system may be significant in the central nervous system, and treatment with bicarbonate may be indicated.

4. Electrocardiograms should be obtained, and patients with abnormal EKGs should be monitored for several days. The incidence of neuropsychiatric complications is higher in older patients with decreased cardiac reserve. Consequently hypotension and arrhythmias should be actively treated.

5. All patients should be treated with hyperbaric oxygenation if possible.

6. Tranquilizing drugs that decrease REM sleep should be avoided.

7. Because of the occurrence of edema, treatment with an agent such as dexamethasone or mannitol should be considered (26). Normal cerebrospinal fluid pressures cannot rule out central nervous system edema in CO poisoning.

8. Bedrest for 2 to 4 weeks seems necessary to avoid delayed onset of neuropsychiatric symptoms. Although the exact etiology of this delayed onset is not known, there is a clear correlation between the onset of delayed symptoms and increased patient activity. Any activity that involves decreased perfusion of the central nervous system or increased central nervous system metabolic activity should be avoided (28). ECT should be particularly avoided following exposure to carbon monoxide (31).

Although these measures are more extensive than those currently used in most hospitals, we think they are medically indicated and economically feasible. The cost of long-term psychiatric hospitalization for patients with permanent neuropsychiatric sequelae of CO damage is much greater than the cost of prompt and appropriate management of patients exposed to carbon monoxide. Because the pathology and pathophysiology of all types of anoxic encephalopathy appear to be similar to carbon monoxide poisoning, it may be worth considering extending this treatment regimen to all patients who have experienced anoxic episodes.

Psychiatric Presentations of Seizure Disorders

BY JOHN LAWALL, M.D.

Seizure disorders may present with signs and symptoms that are usually associated with psychiatric disorders. Physicians must be alert to this possibility; they should use careful history taking in conjunction with EEGs to avoid misdiagnosing certain cases of psychomotor, petit mal, and grand mal epilepsy.

ONLY FAIRLY recently has epilepsy been recognized as a group of disorders that are primarily organic in origin. Although paroxysmal brain discharges may disturb affect, thinking, and behavior, unusual symptoms of epilepsy may be thought to represent so-called functional disorders. An automatic assumption that bizarre symptoms indicate psychiatric disorders or a narrow view of the manifestations of seizure disorders may lead to misdiagnosis, especially in emergency rooms, crisis centers, and similar situations.

The primary care physician and the psychiatrist must be alert to the possibility of psychiatric presentations of seizure disorders and take appropriate steps to ensure accurate diagnosis. Even though pressure may exist in some settings to forgo seemingly excessive lab tests and to leave physical examinations to other physicians, our patients may benefit if we as psychiatrists use our neurologic expertise. The incidence of misdiagnosis of seizure disorders is probably small, but to the individual patient the significance is great.

Although the incidence of psychiatric disorders is greater in epileptics than in the general population (1, 2), my concern here is with those symptoms which occur as part of the basic seizure disorder. Grand mal, psychomotor, and petit mal epilepsy are the seizure types I will discuss, although it is conceivable that other seizure types could also be mistaken for psychiatric disorders.

PSYCHOMOTOR EPILEPSY

Psychomotor epilepsy is perhaps the quintessential example of a disorder on the borderline between psychiatry and neurology. It may manifest in such symptoms as laughter (gelastic epilepsy), hallucinations, coprolalia, assaultive behavior, hypo- and hypersexuality, and hypergraphia, among others. Occasionally a picture suggesting a full-blown psychosis may be seen, especially if the aura is complex and vivid. Flor-Henry (3) has characterized the aura as analogous to a transient psychosis. Déjà-vu, jamais-vu, depersonalization, derealization, paranoia, changes in mood, and hallucinations may occur in an organized fashion during the aura. It has been maintained that psychomotor epilepsy predisposes one to schizophreniform psychosis (2, 3).

Complex behavioral syndromes have also been reported as equivalents of psychomotor epilepsy. Abdominal epilepsy (4), characterized by abdominal discomfort, nausea, vomiting, and postictal confusion, is one such syndrome (4). According to Babb and Eckman (4), such patients are often labeled neurotic. Twilight states with complex automatisms have also been reported. In the case reported by Escueta (5), confusion (with some responsiveness to the environment), automatisms, and amnesia were accompanied by 1.5 to 4 cps high-amplitude EEG tracings and represented a form of psychomotor status epilepticus.

GRAND MAL EPILEPSY

Grand mal epilepsy is somewhat less dramatic from a psychiatric standpoint, but it can still present with psychiatric symptoms. Confusional states, psychotic states, and prolonged twilight states may occur (5, 6). Occasionally a patient with grand mal seizures may even simulate such seizures when malingering or during a conversion reaction (7). Probably the most common source of error in this area is in not obtaining an adequate history when confronted with some of these symptoms.

PETIT MAL EPILEPSY

Of least importance because of its relatively low incidence is petit mal epilepsy. However, we have often heard anecdotally of a child "diagnosed" by a teacher, parent, or other lay person as lazy, depressed, having a learning disability, etc., when in reality he/she is suffering from petit mal. In addition to the brief staring spells, petit mal has recently been reported to produce affective manifestations. Wells (8) reported two cases in which depression characterized by withdrawal, veiled hostility, and suicidal thoughts was accompanied by the typical 3-cps spike and wave pattern of petit mal. It

Dr. LaWall is Treatment Director, Mental Health Services, St. Mary's Hospital and Health Center, 1601 West St. Mary's Rd., Tucson, Ariz. 85703.

is also of note that the onset in this case was in late life, even though it is often said that this disorder does not have adult onset.

CASE REPORTS

The following case reports will demonstrate some of the principles to keep in mind in diagnosing epilepsy with predominantly psychiatric symptoms.

Case 1. A 28-year-old woman was brought to the emergency room by her mother, who said that she had been acting strange for about a week. A psychiatric consultation was requested by the intern. The patient was found to be awake but unresponsive to questioning, although she seemed to want to reply. Being unable to do so, she got up from her bed and attempted to leave once but was easily led back to bed. Finally, she was asked whether she was having difficulty thinking, in response to which she simply nodded. The mother could only add that her daughter had seemed distant and quiet, had eaten little, and had paid little attention to her husband and children for about a week; she had been well before this.

After rather extensive but fairly unproductive questioning, the mother was asked if her daughter had convulsions. She said she thought so. Further questioning revealed that the patient had had grand mal seizures for about 2 years but had not been evaluated. Her mother recalled that about a week before admission the patient had been found semiconscious on the bathroom floor at home. An EEG was obtained and a constant pattern of slow high-voltage waves was found. A diagnosis of epileptic twilight state was made and the patient was admitted for further neuropsychiatric evaluation.

This case illustrates the need to consult family members in taking histories, especially when the patient's sensorium is clouded, and the need to consider organic causes when the patient's consciousness is altered. Fortunately, an EEG could be obtained on an emergency basis.

Case 2. A 26-year-old man was sent to the emergency room by his family physician with the brief statement that he was "psychotic and needed hospitalization." The patient said that he had smelled acetylene gas at work. Concerned about a possible explosion, he investigated, and found tanks of gas on the roof of his shop pouring into the air-conditioning system. He called the fire and police departments, but they could find nothing wrong and suggested that the patient see a physician.

A psychiatric consultation was requested in the emergency room and no history of behavioral problems could be elicited from the patient or his wife on routine history taking. He denied drug use and there was no evidence of delusions or hallucinations on mental status examination. The patient was puzzled about what had happened. However, further questioning revealed a history of short lapses of consciousness, one of which had resulted in a serious car accident, and the fact that the patient had once been in a building during a gas explosion.

Psychomotor epilepsy was suspected and, following a neurological examination, an EEG was obtained. This revealed frequent random sharp spikes superimposed on an 8–13 cps background in the left temporal area. He was then admitted to the neurology service, where idiopathic psychomotor epilepsy was diagnosed.

This type of case presents the greatest diagnostic problem. There is already a psychiatric label, and the symptoms are consistent with a psychiatric disorder. However, the isolation of the symptoms in time, the bewilderment of the patient and his spouse, and the negative history are inconsistent with most psychiatric disorders. The fact from the history that led to a strong suspicion of a seizure disorder was the patient's lapses of consciousness. Thus, we should search for alterations in consciousness in the history in many psychiatric cases.

Case 3. An 18-year-old girl was referred for admission to the psychiatric service because of a history of violent outbursts. She stated that at times a feeling of rage, with or without provocation, overcame her and she became very violent, usually destroying property and occasionally attacking people. She said that after these episodes, which lasted only minutes, she felt drained, remorseful, and somewhat confused.

Psychiatric evaluation revealed a rather immature, somewhat depressed young woman with a long-standing history of conflict with her parents. Her mother had been in a psychiatric hospital for several months when the patient was 5 years old. Psychological testing supported the evaluation findings and revealed no significant signs of intellectual deficit.

Neurological work-up revealed some drift of the left arm on sustained extension and an EEG with right temporal spiking. Brain scan and cerebral angiography were negative. The neurological consultants were reluctant to diagnose epilepsy. However, the patient was tried on 300 mg/day of diphenylhydantoin (Dilantin) and remained free of such episodes until she was lost to follow-up some 8 months later.

This case illustrates the difficulty in defining epilepsy. While the patient did not have a typical psychomotor seizure, she did have paroxysmal outbursts of ego dystonic behavior with an EEG that suggested a seizure disorder. This kind of clinical picture has been called "episodic dyscontrol" and has been studied by Maletsky (9) and others. In his series, as in the present case, diphenylhydantoin was helpful in controlling such outbursts. Thus, even in the face of some ambiguity, clinical suspicion should lead to diagnostic consideration of a seizure disorder.

CONCLUSIONS

There is a wide range of disturbances in behavior, thought, and affect that, although they are usually associated with psychiatric disorders, may be seen as symptoms of epilepsy. Such symptoms may be the presenting complaints in undiagnosed cases of epilepsy. In order to ensure accurate diagnosis, physicians should maintain a high degree of suspicion of this possibility. Family members should be interviewed, and the periodicity of symptoms and any alterations of

consciousness should be noted. In addition, electroencephalography should be used on an emergency basis in such cases.

Decreased Blood Platelet MAO Activity in Unmedicated Chronic Schizophrenic Patients

BY EDWARD F. DOMINO, M.D., AND SUMATHY SAMPATH KHANNA, PH.D.

The authors found lower platelet monoamine oxidase (MAO) activity in 13 unmedicated chronic schizophrenic male patients in comparison to 13 mentally normal control male subjects—a finding that agrees with previous studies showing MAO activity to be low in the platelets of chronic schizophrenic patients. The authors urge that studies exploring endocrine factors and the role of hospitalization be undertaken to attempt to explain this finding.

THE RECENT FINDING that brain monoamine oxidase (MAO) activity of deceased chronic schizophrenic patients was normal (1) agrees with findings of other investigators (2–4). Reports of abnormally low platelet MAO activity in chronic schizophrenic patients (4–6) are therefore surprising. Furthermore, normal MAO platelet activity in acute schizophrenic patients has also been reported (7–9).

Inasmuch as drug medication cannot easily be controlled for the vast majority of psychiatric patients studied, it seemed important to confirm that platelet MAO activity was decreased in a group of unmedicated chronic schizophrenic patients. We have had a unique opportunity to study a group of drug-free chronic male schizophrenic patients given a nutritious, vitamin-supplemented diet and housed in a pleasant research ward where physical exercise and occupational therapy were readily provided. This group of chronic schizophrenic patients was highly selected on the basis of being formerly drug-resistant. Because these patients did not respond favorably to neuroleptic medication and because of the possibility of undesirable long-range side effects, all psychoactive medication was withdrawn for a minimum of six months.

Dr. Domino is Head, Laboratory of Pharmacology, the Lafayette Clinic, 951 East Lafayette, Detroit, Mich. 48207, and Professor of Pharmacology, University of Michigan, Ann Arbor, Mich. Dr. Khanna is a Research Associate, Department of Pharmacology, University of California, San Francisco, Calif.

This work was supported in part by a grant from the State of Michigan for schizophrenia research.

METHOD

Subjects

A total of 13 chronic schizophrenic men and 13 control (mentally normal) men were studied. The criteria for inclusion of each patient in the study were similar to those previously described (1). The control subjects consisted of drug-free men from 20 to 41 years of age, chosen from Lafayette Clinic personnel and medical students with normal medical histories and psychiatric status. All of the control subjects had been drug-free for one to two months prior to their participation, except that acetylsalicylic acid and ethyl alcohol were allowed on rare occasions. However, these drugs were never allowed during the 24-hour period immediately preceding blood withdrawal.

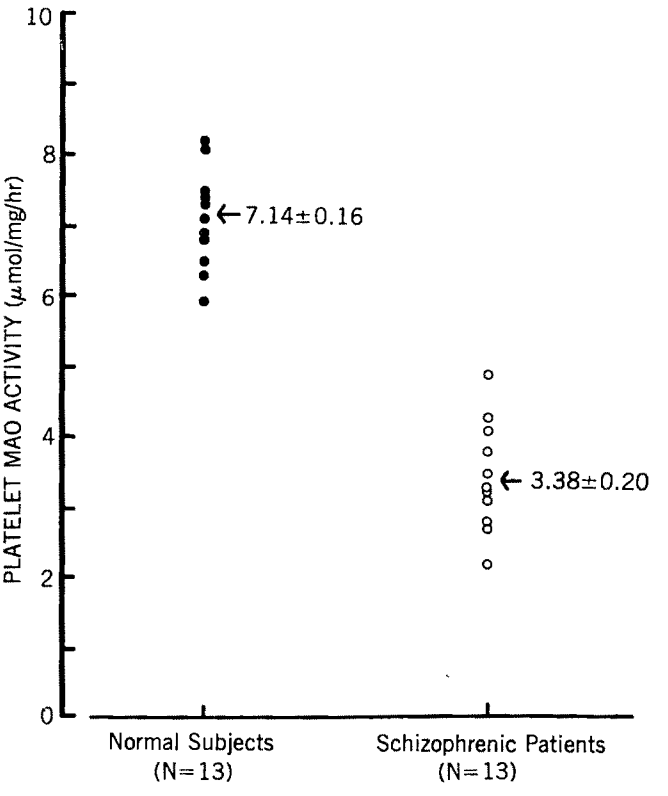
All subjects were instructed to go about their usual daily activities. Thus the control subjects as a group probably had less exercise than the patients, for whom recreational therapy was vigorous. Grossly overweight subjects were excluded except for matching purposes with an occasional overweight patient.

The chronic schizophrenic patients ranged in age from 28 to 44 years. All had been mentally ill since adolescence or young adulthood. They had all received neuroleptic medication at one time, some for many years, but had shown no significant therapeutic benefit. Hence, medication could ethically be stopped at least six months prior to the study.

The patients showed classical primary symptoms of schizophrenia of the process type. They were on a diet of 2300 calories a day, with multivitamin and mineral supplements (MYADEC) given once a day. The control subjects were asked to eat a balanced diet and to take a vitamin supplement.

Procedure

All patients and subjects were asked to fast overnight, and a blood sample was drawn between 7:30 and 8:00 a.m. the next morning. Fifty milliliters of venous blood was drawn with plastic syringes into an ACD solution (acid-citrate-dextrose formula A, Becton-Dickinson Co.). Samples were immediately placed in ice. Platelets were separated in a refrigerated centrifuge using several different spins. The first was spun at about 175 g, the second at about 300 g, and the final at about 600 g. The platelet-rich plasma was separated from red cells with a silicone-treated pipette.



Subsequently, the platelet-rich plasma was transferred to a small plastic centrifuge tube and centrifuged at 3000 g for 5 minutes. A pellet of platelets remained in the bottom, and the platelet-poor plasma was removed. The platelets were then rinsed gently with 0.9% NaCl to remove plasma, by placing 1 ml of 0.9% NaCl into the tube from a pipette, inverting the centrifuge tube, and allowing the fluid to run out.

Platelet MAO activity was assayed using ^{14}C-tryptamine to form ^{14}C-indole acid aldehyde (which can be further oxidized by aldehyde dehydrogenase to form indoleacetic acid [10]). In addition, platelet protein was determined (11). Platelet MAO activity was expressed in micromoles of substrate per milligram of protein per hour. The reaction mixture was incubated for 15 minutes at 37° C and was terminated by the addition of 0.1 ml of concentrated perchloric acid.

RESULTS

Platelet MAO activity for control subjects and drug-free chronic schizophrenic patients showed no overlap in level of activity between the two groups (see figure 1). The mean platelet MAO activity was 3.38±0.20 μmol/mg of protein per hour for the drug-free chronic schizophrenic patients and 7.14±0.16 μmol/mg of protein per hour for the mentally normal control subjects.

FIGURE 1
Scattergram of Platelet MAO Activity for Control Subjects and Drug-Free Chronic Schizophrenic Patients

This difference was highly statistically significant using a group-comparison t test ($t=14.7$, $p<.001$). The mean age of the chronic schizophrenic patients was 36.5±1.8 years and of the control subjects 32.2±2.4 years. This difference was not statistically significant.

DISCUSSION

Platelet MAO activity in psychiatric populations has been studied by many investigators and has been found to vary markedly depending upon psychiatric state as well as genetic and hormonal factors. Nies and associates (4), Murphy and Wyatt (5), Wyatt and associates (6), and Meltzer and Stahl (7), using tryptamine as well as other substrates, reported that platelet MAO activity was significantly lower in chronic schizophrenic patients than in control subjects. Meltzer and Stahl (7) pointed out that platelet MAO activity was lower in acute schizophrenic patients than in the control subjects only when *m*-iodobenzylamine or tyramine were used as substrates. When octopamine and tryptamine were used, acute schizophrenic patients had normal platelet MAO activity.

Friedman and associates (8) reported that when tryptamine was used as the substrate no differences were found among groups of normal control subjects, patients with acute schizophrenia, and patients with

other psychiatric diagnoses. In their control group, women had significantly higher enzyme activity than men. Female schizophrenic patients showed a trend toward lower activity than did female control subjects, but the female patients did not differ from the male schizophrenic patients. Friedman and associates suggested that platelet MAO activity may be related to hormonal, dietary, or genetic factors but not to psychiatric diagnosis. These findings are consistent with those of Wyatt and associates (6), who have suggested that MAO activity in platelets is a possible genetic marker for vulnerability to schizophrenia.

Endocrine factors are extremely important and should be given prominent attention. It has been shown in studies with rats that estrogen and corticosteroids decrease MAO activity while progesterone increases MAO activity; furthermore, there are marked variations in various tissue (including brain) MAO activities as a function of the estrous cycle (12). Human platelet MAO activity varies as a function of the menstrual cycle and is lowest just before menses (13).

It should be pointed out that platelet MAO activity and brain MAO activity are probably unrelated. For example, human brain MAO consists of four isoenzymes (14), while human platelet MAO is electrophoretically homogenous (15). Furthermore, on the basis of substrate specificity brain MAO has been suggested to be both A type (dopamine, norepinephrine, or 5-hydroxytryptamine as substrate) and B type (benzylamine as substrate). Platelet MAO is primarily B type (16). Tryptamine, the amine substrate used in this study, is oxidized by type A and B MAO.

Both Wyatt and associates (6) and Nies and associates (4, 17) have emphasized the importance of a genetic factor by studying the levels of platelet MAO activity in families with lowered enzyme activity.

Murphy and Weiss (18) have reported reduced platelet MAO activity in bipolar depressed patients. Nies and associates (4, 19) have emphasized the relationship between MAO activity and aging as well as mental depression. Especially important is the finding that MAO activity in the brain dramatically increases with old age. It is of interest that in this study the chronic schizophrenic patients as a group were slightly older than the control subjects, but this trend was not statistically significant. The patients still showed a lowered platelet MAO activity.

It would appear that the finding of a 50% decrease in platelet MAO activity in drug-free chronic schizophrenic male patients is reliable, for it has now been replicated in at least five different laboratories. Three laboratory studies have shown that acute schizophrenic patients do not have such a decrease. This suggests that factors secondary to the illness may have an important role. In the present study, the schizophrenic patients ate a nutritious diet and had plenty of exercise, so that such environmental factors would seem to be ruled out. However, a chronic debilitating disease, developing in young adulthood and lasting for many years, could have obvious and important effects secondary to hospitalization, as is made evident by the many reports of biologic abnormalities in psychiatric patients (20–25). The role of endocrine changes also is important. A chronic schizophrenic male population similar to ours has been shown to have lowered plasma dehydroepiandrosterone levels (26).

Another point that should be kept in mind is that unmedicated chronic schizophrenic patients tend to have elevated platelet 5-hydroxytryptamine (27). Although platelet MAO is of the B type, there may be some interaction between endogenous platelet 5-hydroxytryptamine and exogenous ^{14}C-tryptamine added as the substrate. Further studies exploring the possible role of endocrine factors and duration of hospitalization are clearly needed to explain our finding of lowered platelet MAO activity in chronic schizophrenic male patients.

Consultation-Liaison Psychiatry: Current Responsibilities

BY WALTER A. BROWN, M.D., AND ERIC M. JACOBSON, M.D.

The authors describe their experiences as consultation-liaison psychiatrists in two general teaching hospitals. Current medical house staff members appear to be more aware of the importance of psychosocial issues in patient care than were interns and residents in the past. Consultation-liaison teaching may now focus on the application of this psychologic awareness to patient management, the correct use of psychotropic drugs, and the differentiation of delirium from functional psychoses.

THE CONSULTATION-LIAISON psychiatrist has traditionally focused his teaching efforts on sensitizing medical students and house staff to the relevance of psychosocial issues in medical illness and management, interview technique, personality assessment, recognition and management of psychiatric syndromes, and concepts of psychogenicity and psychosomatic medicine (1, 2). However, the reluctance or inability of medical house staff to think in psychologic terms and accept the importance of psychosocial variables in medical practice has been noted as a primary obstacle to these teaching efforts (2, 3). The orientation of nonpsychiatric house staff to "disease" rather than "person" has been sufficiently frustrating to liaison teaching efforts to lead McKegney (3) to suggest that such teaching should be directed instead toward medical students.

Much of the literature regarding consultation-liaison psychiatry records the experiences of the pioneers in this area, who did their initial work before 1960. Our experience over the past academic year with medical house staff and medical students rotating through teaching medical services suggests that the approach of house staff of the 1970s to psychologic issues may be different and that the teaching role of the present-day consultation-liaison psychiatrist may require a different emphasis.

One of us, W.A.B. (a psychiatrist), makes liaison rounds once weekly with medical house staff and students rotating through medicine at two general hospitals affiliated with a medical school; he also provides formal psychiatric consultation to teaching medical and surgical services. The other, E.M.J. (a second-year resident in psychiatry), makes morning work-rounds with medical house staff two times weekly; in addition, he provides psychiatric consultation to the

Dr. Brown is Director, Psychiatric Consultation-Liaison Service, Veterans Administration Hospital, Davis Park, Providence, R.I. 02908, and Assistant Professor of Psychiatry, Brown University, Providence, R.I. Dr. Jacobson is senior resident in the Department of Psychiatry, Brown University, Providence, R.I.

The authors would like to thank Drs. Thomas Laughren and Demmie Mayfield for their help in preparing this paper.

medical and surgical services of a general hospital. Through these activities we have had contact with about 50 medical residents and interns from a variety of medical schools and geographic areas. Neither general hospital had psychiatric consultation-liaison teaching prior to this academic year.

TEACHING AREAS

Psychopharmacology

Although clinical psychopharmacology has been mentioned by previous authors as one of the teaching areas of the consultation-liaison psychiatrist, it is not one of the teaching functions that has been emphasized (1). A considerable portion of our time was taken up in teaching proper use of psychotropic drugs. Our knowledge of psychopharmacology was probably called upon as frequently (if not more frequently) as our fund of information about psychodynamics and psychosomatic medicine. Medical house staff seemed to be aware of the general classes of psychotropic drugs but had only a vague sense of how and when they should be used. Much of our teaching in psychopharmacology was directed toward defining those conditions appropriate for treatment with specific psychopharmacologic agents; for example, indicating the type of depression most appropriate for the use of tricyclic antidepressants and identifying the target symptoms of these medications. Staff members typically tended to prescribe neuroleptics and tricyclic antidepressants in dosages far below the therapeutic level and also tended to prescribe benzodiazepines indiscriminately. In addition, the side effects of psychotropic drugs and the organic conditions that contraindicate their use were not generally appreciated. After appropriate explanations, medical house staff members appeared quite willing to prescribe full therapeutic doses of these medications.

This emphasis on psychopharmacology is, of course, partly a result of the current availability and effectiveness of a variety of psychopharmacologic agents. It may also reflect a trend among young medical professionals to view the psychopharmacologist, the manipulator of brain neurochemistry, as the current "wizard" in psychiatry.

Recognition of Delirium

Although house staff members were familiar with the features of the chronic brain syndromes, the features differentiating delirium from functional psychoses were not generally appreciated, and the subtle manifestations of delirium were not usually recognized. There was a tendency to attribute psychotic behavior and confusion to schizophrenia, without an adequate medical or psychiatric evaluation for the presence of an organic etiology. House staff tended to rely on whether patients were oriented or not as the indicator of cognitive functioning.

The readiness of house staff to make diagnoses of functional psychosis and their relative insensitivity to the manifestations of delirium may be related to the fact that the organic brain syndromes, particularly delirium, fall somewhere between the cracks in medical school teaching; they are not emphasized by the departments of psychiatry, neurology, or medicine. Clinical clerkships in psychiatry tend to focus on the functional psychoses rather than on the organic brain syndromes. We believe, along with previous authors (4), that delirium is underdiagnosed on medical services.

ATTITUDES TOWARD THE LIAISON PSYCHIATRIST AND PSYCHOLOGIC CONCEPTS

Contrary to our expectations, the house staff of the two general hospitals in which we taught were not resistant to our presence, but were instead pleased to have psychiatric consultation-liaison services available. In one hospital the medical house staff itself had initiated the development of liaison psychiatry teaching. We found that residents and interns were aware of the importance of psychologic issues in patient management and almost invariably considered situational stress, personality style, and psychologic symptoms to be worthy of serious consideration in dealing with their medical patients. Thus it became clear that indoctrination regarding the relevance of psychosocial issues in the practice of medicine would not be one of our major functions.

This is not to say that the residents and interns we encountered had a well-developed sense of the role of psychologic variables in medical illness and medical management, or that their psychologic awareness was necessarily reflected in their style of patient care, but rather that they accepted the importance of psychologic issues in their work. This psychologic mindedness of the house staff—their orientation to both person and disease—was in contrast to the attitudes recorded by previous workers. This apparent change in attitude may be related to the social awareness and humanitarian concerns characteristic of the college students of the 1960s and to the increasingly firm place of behavioral science in the medical school curriculum.

DISCUSSION

In developing psychiatric consultation-liaison services in two medical school-affiliated general hospitals over the past academic year, we found ourselves dealing with somewhat different issues than we had expected. This is not surprising in view of the fact that the consumers of our teaching arose out of a different social and medical school context than did their forebears. Although some of our time was spent teaching and discussing concepts of psychosomatic medicine, psychoanalytic developmental psychology, and character style, a considerable portion was spent teaching psychopharmacology and the differential diagnosis of

psychotic behavior. Thus, we feel it is crucial that the psychiatrist who undertakes such teaching should be thoroughly grounded in clinical psychopharmacology and in the recognition and management of organic brain syndromes, as well as in psychosomatic and psychodynamic theory.

The lack of resistance to psychologic concepts and the sensitivity of the house staff we encountered to psychosocial issues may represent a change in attitude from that confronting previous workers. At present, however, this possible change in attitude is more impressive than any apparent change in style of patient care. The important task of current consultation-liaison psychiatrists may be to guide new nonpsychiatric physicians in applying their psychologic awareness to their management of patients.

The Role of the Chief Resident: Expectations and Reality

BY JACK F. WILDER, M.D., ROBERT PLUTCHIK, PH.D., AND HOPE R. CONTE, PH.D.

The job expectations of 35 incoming chief residents were tested by questionnaire when they attended a weekend workshop on leadership and were reexamined after they had had six months' experience on their jobs. Such personal qualities as a sense of humor and persistence and such administrative skills as the ability to exercise authority and set objectives significantly increased in importance six months after these residents began work. The authors recommend educational programs in administration for chief residents.

THE ROLE OF THE CHIEF RESIDENT in psychiatric residency programs has received little systematic examination. However, the Department of Psychiatry at Albert Einstein College of Medicine had a unique opportunity in June 1974 to investigate the attitudes and functions of chief residents in psychiatry from many medical schools throughout the United States. The department offered a weekend workshop designed to increase leadership skills and sensitivities of incoming chief residents. Notices were sent to all medical schools throughout the country, and a total of 65 chief residents decided to attend. During their stay at the workshop, they were exposed to formal and informal course material. In addition, they were asked to complete a questionnaire designed to determine their attitudes concerning the roles they would soon assume as chief residents. This report compares the results of this initial survey with the results of a follow-up survey after the chief residents had had approximately six months' experience on their jobs. Thirty-five of the chief residents completed both surveys.

Dr. Wilder is Associate Dean for Planning and Operations, Dr. Plutchik is Associate Professor, Department of Psychiatry, and Dr. Conte is Research Associate, Department of Psychiatry, Albert Einstein College of Medicine, Yeshiva University, 1300 Morris Park Ave., Bronx, N.Y. 10461.

METHOD

A 46-item questionnaire was constructed.[1] The information used for the development of the items came primarily from two sources. The first was the 19-item questionnaire used by Grant and associates (1) for their resident-staff survey. This questionnaire was based principally on information provided by the proceedings of a panel on the function of the chief resident at the 124th annual meeting of APA, Washington, D.C., May 3–7, 1971. The second source of information for questionnaire items was consultations with

[1]Copies of the complete questionnaire and results are available by request from Dr. Wilder.

several psychiatrists who have supervised psychiatric chief residents.

The questionnaire covered a wide variety of issues relevant to the role of the chief resident: academic skills, personal qualities, administrative skills and practices, relationship between faculty and staff, organizational arrangements, and ways of improving leadership performance. The chief residents were asked to indicate on a scale from 1 to 5 the relative importance of each role or characteristic.

The first questionnaire was administered at the beginning of the workshop, and the second was completed by mail. The reliability of the questionnaire was determined by randomly dividing the questionnaires completed at the workshop into two subgroups. The mean score for each item within each subgroup was computed, and the mean scores for all corresponding pairs of items were then correlated (2). After correction for attenuation, the correlation was found to be +.94, indicating high reliability for the questionnaire.

Thirty-five chief residents, representing 31 colleges of medicine and 20 states across the nation, completed the questionnaire on the two occasions. The mean importance rating for each item at both times was calculated. Tests of significance for paired comparisons (t test) were then performed to determine whether the mean importance rating for each item changed over time.

RESULTS

The most obvious finding of the study was that there was very little change in the mean importance ratings of items after the chief residents had had six months' experience. For example, the item concerned with facilitating communication between house staff and permanent staff was given a mean importance rating of 4.71 at the start of the workshop. Six months later, this item was given a mean importance rating of 4.60. This change was not significant. However, the high rating this item was given on both occasions indicated that the chief residents considered facilitating communication to be an extremely important function. Similarly, at the time of the workshop the chief residents gave a mean importance rating of 1.77 to the question, "How important is it that the chief resident be a fourth-year resident rather than a third-year resident?" At the time of follow-up, the mean rating for this item was 1.91. This item thus appeared to be relatively unimportant at the time of both surveys. The product-moment correlation between the two sets of mean scores was .93. This supports the interpretation of relatively little change in the rank order of importance of most of the items over a six-month period. (The rank order was determined on the basis of the mean rating for each item.)

However, there was a significant change in the mean ratings of 11 of the 46 items over the six-month period. These items, 8 of which increased in importance and 3 of which decreased in importance, are presented in table 1. Also presented are the rank orderings of these items at the two testing periods.

The increases and decreases in importance of the issues dealt with in these 11 questionnaire items may be considered in terms of the discrepancy between the expectations of incoming chief residents and the reality they faced on the job. For example, 1 of the 3 items that decreased in importance concerned the way in which a chief resident is chosen: "How important is it for the appointment of the chief resident to be determined by a vote of his peer residents?" The incoming chief residents, most of whom had been appointed by faculty, had expressed concern at the workshop that their peers might react to their appointments with envy and hostility. A few felt that chief residents should therefore be chosen by their peers. However, after six months in a leadership role, they were apparently more comfortable in their identification with faculty and in their exercise of authority. Therefore, they were less concerned with how their peers might view their selection.

In a similar vein, the chief residents attached less importance to being able to get along with everyone after six months on the job. They apparently came to the conclusion that one could not get a job done without generating a certain amount of conflict and frustration.

The third item that decreased in its mean importance rating concerned research skills. It should be noted that the importance of these skills was relatively low to begin with; it appears that chief residents, like most busy administrator-clinicians, generally have little time for research activities.

Items that increased in importance also reflect the chief residents' greater awareness of the administrative complexities of their positions. It would seem that they had come to their jobs with great expectations of what they could accomplish, overlooking the fact that theirs was a transitional, time-limited role with little authority and with ill-defined responsibilities. As pointed out by Grant and associates (1), the chief residency requires "living with uncertain consequences, divided loyalties, and at times insolvable ambiguity" (p. 503). The second survey revealed a significant increase in the importance attached to exercising authority, telling people what to do even if they do not like it, and setting objectives for the year.

Three personality items increased in importance: having a sense of humor, having an optimistic outlook, and being persistent. After struggling with the ambiguities and frustrations of their administrative roles, the chief residents appeared to realize that their personal sense of well-being and their success in effecting change required a lack of defensiveness, a belief that situations can be improved, and stubbornness in the face of obstacles.

The last 2 items that increased in importance concerned training in leadership skills: an elective seminar on administrative skills and management in a residency training program and the helpfulness of the weekend workshop in becoming a good chief resident.

TABLE 1
Rank Ordering and Chief Residents' Mean Ratings of Importance of 11 Aspects of Their Jobs Before and After Six Months' Experience

Question	Rank Ordering*		Mean Rating of Importance**		
	Before Starting	After Six Months	Before Starting	After Six Months	Significance***
How important is it to have a sense of humor?	12.0	1.0	4.29	4.77	$p<.001$
How important is the quality of persistence in doing the job?	9.0	2.0	4.34	4.71	$p<.01$
How important is it to tell people what to do even if they don't like it?	23.5	10.0	3.74	4.43	$p<.01$
How important is it to have an optimistic outlook?	21.5	14.0	3.77	4.31	$p<.01$
How important is it to set objectives for what you hope to accomplish during your year on the job?	20.0	16.0	3.89	4.29	$p<.05$
How important is it to exercise authority in doing your job?	29.0	18.0	3.49	4.26	$p<.001$
How important is it to have at least an elective seminar on administrative skills and management in a residency training program?	33.0	24.0	3.39	3.97	$p<.001$
How important do you expect this workshop to be in helping you to become a good chief resident?	32.0	27.0	3.35	3.71	$p<.05$
How important is it to be able to get along well with everyone (house staff and permanent staff)?	25.0	33.0	3.71	3.26	$p<.05$
How important are research skills?	38.0	43.0	2.60	2.23	$p<.01$
How important is it for the appointment of the chief resident to be determined by a vote of his peer residents?	37.0	44.0	2.71	2.11	$p<.01$

* 46 items were rank-ordered.
** 5-point scale: 5 =very important, 3 =moderately important, 1 =not important.
*** By t test.

Another way to consider the data is in terms of ranking of items at the time of follow-up. Two personal qualities, sense of humor and persistence, were ranked 1 and 2, respectively. Management skills and practices were the remaining most highly ranked items, e.g., facilitating communication, consistency, and accessibility to staff. Such fiscal and organizational arrangements as a salary premium, a faculty appointment, and the selection process were ranked low at both testing periods. Although these were issues that evoked considerable discussion at the workshop, the chief residents apparently realized even before beginning their jobs that competent people, not organizational procedures, make for results.

In addition to having varying degrees of administrative responsibility, almost all of the chief residents had academic assignments. Skills related to these assignments, usually considered to be the sine qua non for selection of a chief resident, all dropped in importance at the time of follow-up. Teaching skills went from a rank of 2 to that of 12, clinical skills from 9 to 16, and research skills from 38 to 43. The decrease in importance of these academic skills and the increase in importance of management and interpersonal skills probably reflect the realistic demands of the job. In all positions of leadership in an academic setting there is a tendency to underestimate the administrative skills required and to overestimate the opportunities to engage in academic activities. The development of a smoothly running setting is a precondition for the application of academic skills.

One series of items concerned ways of acquiring leadership skills. These items were generally ranked in the middle range. Among these items, a good role model, on-the-job experience, and an elective seminar on administration were judged to be most important, whereas a required seminar, clinical training, and the reading of management literature were viewed as less helpful.

DISCUSSION

The results of the survey have two implications. First, they identify a number of personal character-

istics and administrative skills that chief residents consider to be important in the successful performance of their jobs. This information may be useful to those responsible for selecting chief residents. Second, the survey highlights the difficulties chief residents face in assuming positions of authority and responsibility, usually without previous training or ongoing support. Parenthetically, these difficulties were a major focus in group discussions at the chief residency conference. As has been pointed out by Barton (3), the lack of adequate training is a general problem in the field of administrative psychiatry.

It is reasonable, therefore, to conclude that departments of psychiatry should not allow the chief resident to sink or swim on his own and, possibly, because of failure, become turned off to future leadership positions. Rather, psychiatry departments should view the chief residency as an educational assignment and opportunity that requires a systematic and thoughtful educational program (4). Future research will be directed at examining the administrative careers of chief residents who had special support and training during their chief residency in comparison with those who did not.

The Effect of Haloperidol on Stuttering

BY PETER B. ROSENBERGER, M.D., JULIE A. WHEELDEN, M.ED., AND MADELINE KALOTKIN

Haloperidol was compared with placebo in the treatment of 8 young adult stutterers in a double-blind crossover study involving 6 sequential observations over periods of 6 or 12 weeks. The drug was found to have a significant effect on the percentage of time subjects were dysfluent but not on the number of dysfluencies per minute. The authors discuss possible reasons for this finding.

RECENT STUDIES of the effect of haloperidol on various tic syndromes (1) and especially on the convulsive tics of Gilles de la Tourette's syndrome (2) have led to the suggestion that the drug might be useful in the syndrome of common stuttering. Several studies on this subject have recently appeared in the literature. Tapia (3), studying 11 patients, showed that only 2 of the 6 patients who reported improvement actually depressed the number of nonfluencies in their verbal output. This report commented that "a surreptitious placebo produced relapse." Gattuso and Leocata (4) claimed 80% complete relief in 50 patients aged 5 through 12 but used no control subjects. The study of Wells and Malcolm (5) was placebo controlled and double blind and examined haloperidol in combination with orphenadrine and speech therapy. Of 12 patients on haloperidol, 10 showed improvement as judged by a reduction in the number of nonfluencies per 100 words.

We decided to test the effect of haloperidol on stuttering using a double-blind crossover design and attempting to show repetitive fluctuations in speech fluency as a result of change from placebo to haloperidol over several weeks in a small number of patients.

METHOD

Our subjects were 8 young adult stutterers who were attending a weekly group stuttering therapy session in the Language Clinic of the Massachusetts General Hospital. There were 6 men and 2 women, all between the ages of 20 and 32. The 6 men and 1 of the women

The authors are with the Massachusetts General Hospital, Boston, Mass. 02114, where Dr. Rosenberger is Director and Ms. Kalotkin is Research Assistant, Learning Disorders Unit, and Ms. Wheelden is Speech Pathology Supervisor, Language Clinic; Dr. Rosenberger is also Assistant Professor of Neurology, Harvard Medical School.

This study was supported in part by a grant from McNeil Laboratories, Fort Washington, Pa.

had been stuttering since early childhood; the other woman, according to her own report, had been stuttering since age 12. All had had previous speech therapy, with experience ranging from 1 to 10 years. None had had prior drug therapy. All of the subjects were neurologically intact, of normal intelligence, and gainfully employed. Informed consent was obtained from all subjects after explanation of risks and benefits.

Medication, either haloperidol or an identical appearing placebo, was given uniformly in a dose of 1 mg three times a day. The medication was dispensed to the patients in envelopes at six regular intervals: every two weeks in the case of subjects A and E and weekly in the case of the other 6. Subjects were told that the tablets dispensed to them would contain haloperidol for three of the six study periods and "another medication" for the other three. Patients were assigned by a neutral third party to one of a list of six schedules submitted by the experimenters. Neither the experimenters nor the subjects were aware of which schedule was in effect, and in addition the subjects were not told six schedules might be used.

If side effects to the medication were reported before the particular study period ended, the patient was advised to reduce the dosage of the medication by one tablet per day and to attempt to tolerate the side effects. Three previous subjects, all teenagers, had been unable to complete the study because of inability to tolerate the side effects.

Testing sessions were conducted at the end of each study period (every two weeks in the case of subjects A and E and every week in the case of the other 6). Sessions were videotaped in their entirety by a camera located behind a one-way observation window, of which the subjects were aware.

The sessions tested three speaking conditions: spontaneous conversation, reading, and picture description. In the conversational section, the subject was first asked to identify himself and give some biographical information and then to describe his speech problem briefly. He was next questioned about his activities during the past week and asked his opinion concerning the fluency of his speech. Finally, he was asked to describe any side effects that had occurred during the previous week. In the reading section, the subject was given a written paragraph of about 100 words and asked to read it aloud. Selection of the material was made at random from three standard paragraphs commonly employed by speech therapists to test enunciation of all phonemes in the language. In the third section, the subject was given one of three complex pictures and asked to describe the action in it.

Data concerning the subject's speech fluency were gathered at a later time by an impartial observer. The observer sat viewing the videotape and holding two hand switches, each of which was connected both to a sequential counter and a running time meter. The observer pressed one switch (and held it down) whenever the subject was talking, and the other switch whenever the subject was dysfluent. Thus a measure of both percentage of time dysfluent and of dysfluencies per minute of spoken speech was acquired. The observer made repeated observations of a single session with each subject until two sequential observations differed by not more than 5%; then he continued with single observations of subsequent sessions.

RESULTS

Figure 1 shows the percentage of verbal output that was dysfluent for each subject during the baseline evaluation and in each of the six testing sessions that followed haloperidol or placebo therapy under the conditions of spontaneous conversation, reading, and picture description.

From these raw data we concluded that subjects A, B, C, and F showed a definite response to the drug; subjects D and G showed a probable response, subject E definitely showed no response, and subject H had too low an initial stuttering rate to allow a decision. In addition, the figure indicates a mild general placebo response as a function of time throughout the study.

Comparisons of the performance of all subjects under the three speaking conditions show a general similarity, with some interesting exceptions. Subject A, whose dysfluency in spontaneous conversation frequently rendered him effectively incoherent, was almost entirely fluent when reading aloud, even in the baseline session. Subjects C and E showed a similar pattern, although it was less dramatic. In contrast, subjects D and F were significantly more dysfluent when reading aloud. This finding of varying patterns of nonfluency is in line with the clinical experience of most speech pathologists. Our hypothesis, currently in the process of being tested, is that this difference is related to the stutterer's reading comprehension skills.

Tests for statistical significance of the drug effect were run separately for the three speaking conditions. Figure 2 shows averaged data for spontaneous conversation. Subjects are arranged on the abscissa in order of severity of stuttering according to the baseline measurement. When relative percentages of dysfluency are compared by the Friedman analysis of variance, the significance of the drug effect seems to be related to the severity of initial stuttering. The relationship between severity of initial stuttering and drug treatment results is significant at the .004 level for those subjects who were more than 30% dysfluent at baseline. When this analysis is extended to those who were more than 15% dysfluent at baseline, the significance decreases to $p=.072$; for the entire sample the level of significance is .079.

As may be gathered from figure 1, statistical comparisons for reading and picture description were similar to those for spontaneous conversation, with the exception that for reading, significance was achieved for the five subjects whose baseline dysfluency was greater than 15% ($p=.024$).

Data for stuttering *rate* (number of dysfluencies per

FIGURE 1
Percentage of Time Subjects Were Dysfluent Under Three Speaking Conditions

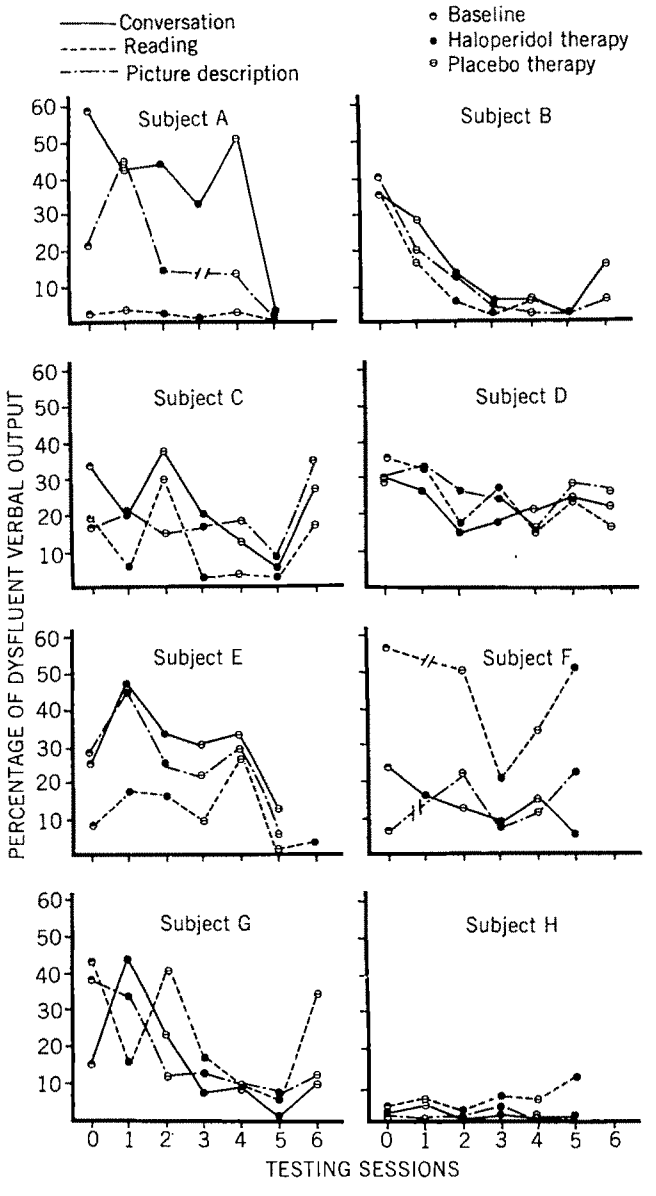

FIGURE 2
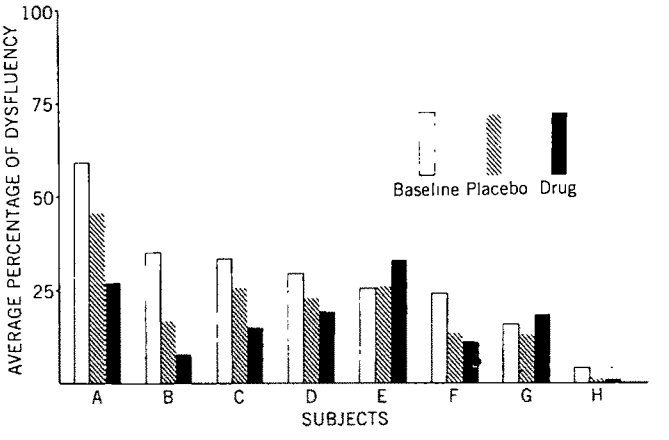
Average Percentage of Time Dysfluent During Spontaneous Conversation



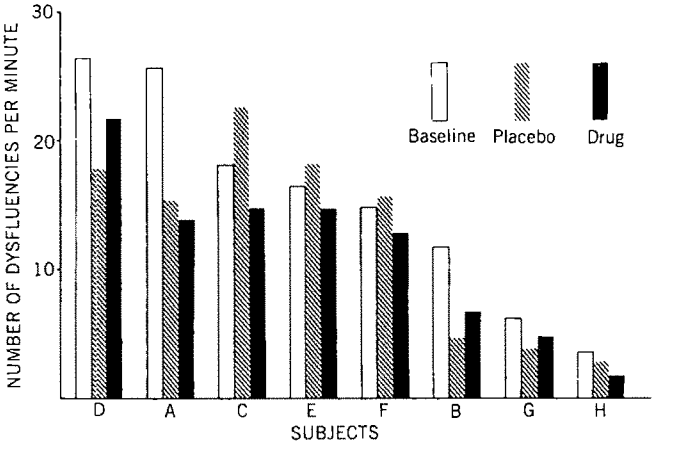


FIGURE 3
Average Number of Dysfluencies per Minute During Spontaneous Conversation

minute) were gathered by counting the number of times a minute during verbal output that the switch registering dysfluency was depressed. Figure 3 shows averaged data for this quantity during spontaneous conversation. Again, subjects are arranged on the abscissa in order of initial severity with respect to this measure. As might be expected, these findings differ somewhat from those for percentage of dysfluency. For example, subjects B and D, whose percentage of time dysfluent improved under the drug, actually showed more dysfluencies per minute; the experience of subject E was just the reverse. In the case of the tonic stutterer, of course, an inverse relationship between these two measurements is to be expected, i.e., a decrease in the number of tonic spasms will result in more syllables per minute, which if they are repetitious will be scored as discrete dysfluencies. This finding confirms the experience of Wells and Malcolm (5), whose findings showed a greater reduction in the amount of time needed to speak 100 words than in the percentage of repetitions as a result of the drug.

Although several subjects, notably C, E, and F, showed significant decreases in their stuttering rate on the drug as compared with placebo, results for the group as a whole did not reach statistical significance by the Friedman analysis.

DISCUSSION

Haloperidol, a butyrophenone, was developed in the course of efforts to increase the analgesic potency of meperidine compounds. According to Janssen (6), who is credited with its synthesis, the drug derives its neuroleptic properties from its substituted propyla-

mine structure, which it shares in common with phenothiazines. Haloperidol accelerates the accumulation and subsequent disappearance of dopamine formed from ^{14}C-tyrosine in the mouse brain (7). It is more potent in this regard than chlorpromazine, which has been shown (8) also to increase the concentration of homovanillic acid in the caudate nucleus of the cat. These findings have suggested a possible mechanism of action of these drugs through central dopamine metabolism.

As we have mentioned, it was the widespread success of haloperidol as a treatment for Gilles de la Tourette's syndrome which suggested that it might be effective with stuttering. The literature on haloperidol with Gilles de la Tourette's syndrome has been exhaustively reviewed by Snyder and associates (2), who have suggested that the apparent effect of haloperidol on central dopamine metabolism might account for the resemblance of the symptoms of Gilles de la Tourette's disease to the side effects of L-dopa therapy and explain the therapeutic efficacy of the drug.

It is our clinical impression from observation of subjects A and C that it is the hesitation and phonemic stoppage of the severe stutterer which are most dramatically affected by haloperidol. We would expect this to be reflected in the measurement of percentage of time dysfluent but not necessarily in dysfluencies per minute. Each of these two patients, under the conditions of severe stuttering, showed a characteristic facial contortion that was almost totally absent from the videotape records taken after haloperidol therapy. Further study may demonstrate that the patients with such severe phonemic stoppage will benefit most from this drug.

Transsexualism in Two Male Triplets

BY EMBRY A. MCKEE, M.D., HOWARD B. ROBACK, PH.D., AND MARC H. HOLLENDER, M.D.

The authors present clinical and case material on two male triplets with aberrant gender identity. Their findings coincide with those of the few family studies reported in which there were two or more transsexual members; they also reveal patterns generally in keeping with the psychological determinants of transsexualism suggested by Stoller.

The authors are with Vanderbilt University School of Medicine, Nashville, Tenn. 37232, where Dr. McKee is Assistant Professor of Psychiatry, Dr. Roback is Associate Professor of Psychiatry (Psychology), and Dr. Hollender is Professor and Chairman, Department of Psychiatry.

The authors wish to thank Dr. Eric Engel, Professor of Medicine, Vanderbilt University School of Medicine, for performing the chromosomal analyses.

FEW REPORTS have appeared of two or more members of a family with crossed gender identities. It therefore seemed important to report on two anatomically male triplets (the third triplet being female) who were studied when they requested sex-reassignment surgery. It is of additional interest that a third cousin, an anatomical male with whom the triplets had had only recent, passing contact, was also being evaluated for sex change.

This paper is based on psychiatric, psychological, and chromosomal studies of the two anatomically male triplets. The sister was unwilling to be interviewed, but information about her gathered from medical records and respondents seems consistent and reliable. In addition, we reviewed records containing medical and sociodevelopmental information about the triplets be-

fore and during their placement in a foster home at the age of 3 years and interviewed an aunt who raised the children after they left the foster home at the age of 5 years. We also obtained some information about the third cousin.

FAMILY HISTORY

The mother of the triplets died 1 hour after their delivery. She was then 23 years old. Little information about her is available.

The father, a tenant farmer and laborer, drank heavily and worked irregularly. As a boy he had been kicked in the head by a mule, resulting in an injury that required the insertion of a silver plate. At the age of 34, when the triplets were 3 years old, he was admitted to a state psychiatric hospital with the diagnosis of chronic brain syndrome with psychosis due to trauma.

Little is known about the triplets' development during the first 3 years of life other than that they were often neglected. When placed in a foster home at the age of 3 years, they were physically and mentally retarded and their speech was incomprehensible. Having received no training in the use of eating utensils, they ate with their hands and scattered food over everything within reach. Since they had seldom received sufficient food, they picked up and ate scraps thrown in the yard for the dogs. The foster parents, described as an above average family, gradually taught them how to use eating utensils and how to play games.

At 5 years of age the triplets were sent to live with an aunt and uncle with whom they remained until they were 18 years old. The aunt described her husband as an alcoholic who was seldom home. Although she divorced him when the triplets were "very young" (she could not recall the exact year), she permitted him to return home for care whenever he became ill. The triplets could remember little about their uncle except that he was seldom home and when he was, he was usually inebriated. The boys felt close to the aunt's two daughters, with whom they played many feminine games (e.g., dolls and tea parties). In high school they dated boys and had many girlfriends.

CASE REPORTS

Case 1. Marvin-Maureen, who was 20 years old when interviewed, was 5 feet 8 inches tall and feminine looking. "She" had long black hair, used makeup, including lipstick and eye shadow, and wore bracelets and earrings. The overall picture was that of an attractive, perhaps even exotic-looking woman.

While in the foster home Maureen had become more outgoing and began to make friends easily. She seemed to be the favorite of her foster parents and developed a strong attachment to her foster mother.

Maureen, who had always felt feminine, began to wear her sister's clothes at the age of 7. Initially her aunt and uncle permitted her to wear only girls' underclothing; not until she was 13 was she permitted to wear feminine outer garments. Her first sexual encounters with boys occurred when she was 7 or 8 years old. She never used her penis in intercourse; she preferred anal intercourse but occasionally performed fellatio. At age 16, she was arrested for cross-dressing and placed in a juvenile detention home for 2 weeks. She was then required to attend weekly therapy sessions with a group of adult male homosexuals, lesbians, and transvestites for a 2-year probation period.

Maureen referred to herself as a "transvestyke" and mentioned her long-standing desire for sex-reassignment surgery. She stated that her life had been miserable in certain respects and would remain so until after the operation. She commented, "Then I will have a new life to live. I want to show my family that I haven't been the trashy person they thought I was." She is currently in business school and hopes to become an executive secretary. If accepted for the sex-reassignment operation, however, she plans to get a new start in another city. She wants to attend college and to become a model.

On psychological testing Maureen scored in the dull-normal range. As would be expected, there was a nonidentification with the culture's prescription for maleness and, specifically, indications of extreme femininity on the Freund Gender Identity Scale (1). Results of the Minnesota Multiphasic Personality Inventory (MMPI) suggested serious underlying pathology. There was the distinct danger that she would become cognitively disorganized under stress. Testing also revealed much clinging dependence on a maternal figure and a lifestyle best characterized as passive-dependent.

Case 2. Jack/Janice dressed as a woman during some interviews but in others (during working hours) she was dressed in male clothing with a definite feminine touch. Her build was delicate and her manner feminine but somewhat less so than Maureen's.

According to a social casework report, Janice, like Maureen, was physically and mentally retarded at 3 years of age. Like Maureen, she had had a strong attachment to her foster mother, but unlike her "sister" she could tolerate brief periods of separation without becoming unduly upset.

Janice had felt like a girl for as long as she could remember and had cross-dressed regularly since the age of 13. Like Maureen, she preferred anal intercourse, dated only men, and avoided all sexual activity involving the use of her penis. Others thought of her as homosexual, and that is how she usually regarded herself. At times, however, she considered herself a transsexual. Many of her social contacts were with bisexuals.

Although Janice was very curious about sex-reassignment procedures, she was ambivalent about having the operation. Part of the ambivalence appeared to be due to her fear of pain. She commented that if she ever had the operation she would want to be a "classy lady," not an "everyday lady." Like her sister, she believed that she would find greater acceptance in another city.

During psychological assessment Janice was anxious and guarded. She was of borderline intelligence, manifested extreme feminine gender identity, and revealed no indication of psychosis. In her character makeup, passive-dependent and hysterical features were prominent.

Case 3. Joan, the anatomically female triplet, refused to meet with us. She was described as being headstrong, stubborn, and independent. Like her siblings, she was probably

of borderline intelligence. It was reported that she lived with a laborer and had one child.

Case 4. Robert/Rennie, the 23-year-old third cousin, was a student in a beautician school when interviewed. She had met the triplets only 2 years before and had had minimal contact with them. Like her two male cousins she was slender and decidedly feminine in appearance. She wore a reddish-brown Afro wig and a small amount of makeup.

Rennie's father had died when she was 4 years old, and she had always lived with her blind mother. She had felt like a female for as long as she could remember, and she began to cross-dress as a child. At 16 she became a female impersonator. She had dated only males, and her sexual preference was anal intercourse.

Psychological assessment revealed little other than the expected elevated score on the Masculinity-Femininity scale of the MMPI. Rennie's IQ was in the average range. Projective tests revealed no serious psychopathology.

Chromosomal Studies

Chromosomal studies, using blood cell cultures on all three patients, revealed 46 XY, normal-looking male cells.

REVIEW OF THE LITERATURE

As recently as 1973 Stoller and Baker (2) wrote, "Although hundreds of male transsexuals have been reported in the literature, there have until now been no reports of more than one in a family." They then presented information about two anatomically male siblings with normal XY chromosome configurations who fitted their criteria of transsexualism. The boys' father was in the service and was home only intermittently during their formative years. As young children, both "girls" preferred female-type activities (e.g., hopscotch and jump rope) and were not discouraged from taking part in them by their mother. Similarly, in 1973 Hore and associates (3) reported on two transsexual male siblings. The "sisters" had been raised primarily by their maternal grandmother, who was described as the "dominant force" in their upbringing.

Sabalis and associates (4) described a case of three siblings who fulfilled Stoller's criteria for male transsexualism (5). Their mother was said to have had excessive contact with her children. Their natural father reportedly was absent from the home much of the time and paid little attention to the children when he was there. When the father died their mother married a man who was "effeminate, submissive, and passive and also spent a great deal of time outside the house."

Green and Stoller (6) described two pairs of monozygotic twins discordant for gender identity; one of these pairs were 8-year-old boys. The prefeminine twin, Paul, was reported to be more attractive and cuddly. Because of an illness at age 3, the year in which gender identity consolidates, Paul spent much time with his mother; his brother was engaged in sports with his father during this period. At age 4½, Paul expressed a preference for typically feminine activities such as playing with dolls, cleaning house, and playing with neighborhood girls. His brother developed conventional sex-role interests such as baseball and kite-flying.

The second set of twins were 24-year-old women. The masculine twin related that since she was the physically larger and stronger of the two, she had been expected to help her father in typically masculine jobs (e.g., roofing the house and doing stone work), while her more fragile sister was given typically feminine tasks to do around the house. Green and Stoller concluded, "Thus, different early childhood events were experienced by both the male and female co-twins, which were in accord with later manifestations of masculinity and femininity."

COMMENT

Theories concerning the cause of aberrant masculine and feminine development are diverse, ranging from prenatal to postnatal factors and from endocrinological to environmental influences. Male-to-female transsexualism has occurred in persons with a presumed male hormone deficiency, usually those with Klinefelter's syndrome (6). A particular type of early mother-child interaction has also been implicated. Stoller (5) has called attention to an excessively strong symbiotic relationship between mother and infant son, remarkable for the degree of body contact. Coupled with this closeness to the mother is the relative absence, physically and psychologically, of the father.

The history of the triplets revealed many patterns in keeping with the psychological determinants suggested by Stoller. During the first 3 years of their lives, the triplets received little mothering or fathering. The closeness of the two little boys and their foster mother, beginning at the age of 3, might be characterized as excessive. According to reports, the foster mother spent enormous amounts of time with the children, attempting to compensate for their previous deprivation and lack of socialization. Little information was available about the foster father's involvement with the children. As noted earlier, the boys tolerated separation from their foster mother poorly.

Later, another woman, the aunt, became the dominant influence in the triplets' lives. Their uncle was an alcoholic who was absent or sickly much of the time. Cross-dressing began at 7 years of age for one triplet and at age 13 for the other. It has continued to the present, with no sexual pleasure ever associated with it. Masculine behavior and interests were not manifested at any time. Sexual fantasies were always of being made love to as a woman by a man.

The findings of this study are especially interesting because of the unusualness of the subjects (triplets) and because the family dynamics coincide with those reported in the few recorded instances of more than

one case of transsexualism in a family. Thus a psychosocial explanation for the development of transsexualism has now been offered for atypical gender identity in triplets, discordant gender identity development in monozygotic twins (6), and for two (2, 3) and three transsexual siblings (4) within one family. Although the authors of these papers favored an explanation for transsexualism based on family dynamics, they also encouraged further research to assess the part played by environmental, constitutional, prenatal neuroendocrinological, and other forces on crossed gender identity.

An Evaluation of Detoxification as an Initial Step in the Treatment of Heroin Addiction

BY AMIRAM SHEFFET, M.A., MARK QUINONES, PH.D., M.P.H., MARVIN A. LAVENHAR, PH.D., M.P.H., KATHLEEN DOYLE, AND HARVEY PRAGER, M.A.

Of 802 voluntary patients admitted to the detoxification unit of a comprehensive treatment system, 69% completed detoxification but only 9.6% of these patients sought long-term treatment. The demographic profile of detoxification patients differed somewhat from that of patients in long-term treatment. The authors suggest that new approaches, including legal pressure, are needed to induce detoxification patients to accept prolonged therapy.

THE TREATMENT approaches to the narcotic-addicted individual are varied; this is due in part to the lack of a precise understanding of the pathogenesis of addiction and to conflicting opinions on the merits of alternative therapeutic modalities (1). One of the oldest and most widely practiced initial approaches to treatment has been the use of detoxification or "unpoisoning." This approach involves prescribing decreasing daily doses of methadone to the narcotic-addicted individual in order to minimize the effects of withdrawal from the drug.

There are few data on the long-term and short-term effects of detoxification and its therapeutic value (2). The available information indicates that the value of detoxification as an effective treatment for drug dependency is questionable (3). Indeed, most data support the notion that detoxification does not reduce or eliminate the frequency of illicit drug use (4). However, Chafetz and associates (5) reported in 1962 that it was possible to engage unmotivated alcohol addicts in significant treatment by having a detoxification program available.

The Division of Drug Abuse of the Department of Preventive Medicine and Community Health of the New Jersey Medical School, Newark, maintained an inpatient detoxification unit from September 1969 to May 1973. This facility was one component of a comprehensive, multimodality treatment system that has

been in operation since 1969 through funding from the National Institute on Drug Abuse (6). The primary objective of the detoxification unit was to assist drug-dependent patients in becoming drug free before entering long-term treatment in another component of the comprehensive system.

DESCRIPTION OF THE UNIT

At its peak capacity the unit included 6 beds for men and 2 for women in the Martland Medical Center, the major teaching hospital of the New Jersey Medical School. Patients were admitted voluntarily and without legal pressure for, in most cases, a 5–7 day period. Each individual seeking admission was required to appear at the hospital during the regular working hours for a comprehensive interview on health problems and history of drug use. The demand for the unit's services usually resulted in a 2–10 day waiting period between the initial interview and admission.

Upon admission to the unit each patient was placed on daily doses of methadone in decreasing amounts. The usual initial daily dose was 40 mg, but in some cases up to 80 mg were given if the patient's history, symptoms, and physical examination suggested that 40 mg would be inadequate. Methadone was generally administered over a 5-day period.

Staffing for the unit reached a maximum of 4 registered nurses, 3 nursing assistants, and 1 ward clerk. Medical services, along with other supportive services, were coordinated by case expeditors from the drug abuse clinic. These workers were paraprofessionals with a high school diploma or equivalent and at least 2 years of experience in a drug abuse counseling program.

The physical facilities of the unit were similar to those of any traditional older hospital ward, with the men's beds in a large room and the women's beds in a smaller room across the hall. The ward was not locked; security services were provided by a uniformed private guard. All patients agreed to abide by the following restrictions: no visitors, no violence, and no drug use.

Television was the only recreational facility provided, and planned activities for the patients were minimal. One structured activity was a weekly orientation session designed to familiarize patients with treatment modalities available to them after detoxification. The available treatment alternatives included methadone maintenance, counseling for ambulatory drug-free patients, and 1 of the 3 residential therapeutic communities within the system. Four hours were set aside for each orientation session.

This study was undertaken to evaluate the performance of the detoxification unit in achieving its goal of assisting drug-dependent patients to enter long-term treatment. It was also designed to address the broader issue of the role of detoxification in a comprehensive treatment program for heroin addiction.

METHOD

The primary sources for the data base were the 6 affiliates comprising the New Jersey Medical School treatment system and the drug abuse clinic at Martland Hospital. Upon entering the detoxification unit each patient completed a drug registry form (7). Registration data were coded and punched onto tabulation cards for data processing in order to analyze the epidemiological, sociological, and medical correlates of drug addiction. A computerized system for monitoring patients was designed with the capability of providing comprehensive statistical data on the movement of patients within the confines of the treatment system. All data were screened automatically for consistency and accuracy, and errors were promptly corrected (6).

The variable-length records that were generated by the monitoring system were structured and merged with the drug registry information by means of a summarizing computer program. The *Statistical Package for the Social Sciences* (8) was used to analyze the structured files.

RESULTS

This analysis covers the time period between February 1, 1971, and May 31, 1973. During this period a total of 802 patients were admitted to the detoxification unit; of that number, 552 (69%) eventually completed detoxification. There were 1,028 individual attempts at detoxification (on the average, 1.3 attempts per patient); 226 patients entered the unit 2 or more times.

The age and race of 11 patients could not be ascertained. Of the others, almost half (44%) were black, male, and 21 years of age or older; 24.6% were black, female, and 21 years or older.

Sixty-one percent of the patients who entered detoxification as the first phase of drug treatment completed it on the first attempt. When comparing each demographic subgroup's rate of success in completing detoxification treatment with the overall success rate of 61%, it appeared that patients who were 20 years old or younger had a higher than average success rate (72%, which is statistically significant [$p<.05$, z test for standard proportions]). Students had a high (79%) success rate. On the other hand, white patients had a low (51%) success rate. We have compared other demographic variables including residency, occupation, marital status, education, duration of drug abuse, total convictions, and time in jail. Success in completing detoxification did not correlate with any of these demographic characteristics.

Only 53 (9.6%) of the 552 patients who completed the prescribed detoxification treatment sought further long-term treatment within 4 weeks after leaving the detoxification unit.

We then compared the demographic characteristics of addicts admitted to the detoxification program with those entering the 6 treatment programs under our pur-

view (treatment patients). Only 53 of the latter entered treatment after detoxification; the other 2,678 entered treatment directly. The detoxification group had greater percentages of blacks (84% versus 63% treatment patients) and of Newark residents (83% versus 48% treatment patients). Almost half of the detoxification group came from the central ward of Newark and manifested deficiencies in education and work skills. The detoxification program included proportionately more female patients than the long-term treatment group (35% versus 24%) as well as a larger group of patients 26 years of age and older (38% versus 28%).

DISCUSSION

Successful detoxification could be judged by two outcomes: completion of the prescribed course of detoxification and commitment to long-term treatment.

With 69% of the patients eventually completing the prescribed course of detoxification, the first objective appears to have been achieved. Others have proclaimed success with a far smaller percentage of patients completing detoxification (2). We were unsuccessful in regard to the second outcome objective. Our findings in this area confirm those of Glasscote and associates (1).

O'Malley and associates (4) reported that outpatient detoxification was an utter failure regardless of patients' demographic characteristics; very few patients completed detoxification, and there were no candidates for long-term drug treatment. Bass and Brown (9) implied that younger patients may be suitable candidates for detoxification followed by long-term treatment and suggested that older patients are better off in a methadone maintenance program. Aron and Daily (10) reported that 23% of their detoxification patients entered significant treatment, but 86% of these patients were under legal pressure to do so.

Renner and Rubin (2) noted that patients with a short history of heroin use and small daily habit are more likely to succeed in detoxification; they concluded that successful detoxification is related to commitment to long-term treatment. Our study does not confirm these findings. Young patients, who were the most successful in completing detoxification, showed the least interest in further treatment, and it seems that success in regard to the first outcome measurement does not imply success in the second outcome measurement.

The group of patients who sought detoxification was somewhat different demographically from the long-term treatment group. They were more likely to be black, female, older, and Newark residents. These patients entered detoxification for a variety of reasons including a true determination to stop drug use, a desire to reduce the level of addiction, inability to maintain their habit, and pressure by the courts to solicit detoxification services (4). Most of our patients were not able or ready to maintain a long-term commitment to drug treatment even though the detoxification unit was intended as a beginning of the rehabilitation process. However, the unit did provide a needed service for this particular population.

The program was useful in another respect. Although 76% of the patients who entered detoxification did not attempt further treatment or repeat detoxification as of July 31, 1974, of those detoxified patients who eventually did enter long-term treatment, 80% continued beyond the initial 4 weeks, a better than average retention rate.

We believe that our patients were often difficult to deal with in part because of lack of daily structured activities. Other than the medication times, mealtimes, and the weekly orientation sessions, structured activities were nonexistent, and this created boredom and encouraged acting out behavior. In addition, many of the personnel were not well versed in counseling techniques and therefore were not adequately equipped to deal with this difficult and demanding population.

It is obviously incumbent upon treatment staffs to continuously evaluate their programs in an attempt to improve them. We closed the detoxification unit and have now reopened it in a new environment with special attention to counseling and structured activities. It will be interesting to see whether the proportion of patients entering long-term therapy increases significantly.

The observed differences between patients in long-term treatment and those entering and completing detoxification suggest that these 2 groups represent different populations with different degrees of motivation for treatment. It thus may well be that detoxification as a part of long-term treatment will only succeed with a large proportion of patients if there are legal restrictions that compel the individual to accept more prolonged therapy.

The Use of Problem-Oriented Medical Records in Community Mental Health Centers

BY GARRY M. VICKAR, M.D., AND MARIJAN HERJANIC, M.D.

The authors' questionnaire survey of 147 community mental health centers revealed that 36 (24%) were using problem-oriented medical records (POMR), 34 (23%) planned to use them, 23 (16%) were uncertain, and 54 (37%) had not considered using them. According to the responses of centers that were using POMR and the authors' experience, the advantages of POMR in psychiatry are similar to their advantages in other specialties, and the difficulties in implementing this system are related to the definition of "problems."

WEED'S INTRODUCTION of problem-oriented medical records (POMR) (1) has led to a reevaluation of record keeping in many medical centers. Following the adoption of this system, publications appeared endorsing POMR and encouraging their acceptance in all specialties of medicine (2–4). More recently there has been some questioning and attempts at critical evaluation of this new approach (5, 6). Less is known about the use of POMR in psychiatric practice than in other medical specialties. Considering the many advantages claimed for POMR in psychiatry (7), we were surprised to find only an occasional report of their use in this field (8, 9). It may be that psychiatrists have benefited from the experience of colleagues in other branches of medicine (10, 11) and approached the subject with caution.

The POMR was first used in the inpatient service of Malcolm Bliss Mental Health Center, St. Louis, Mo., on July 1, 1974. We wondered about the extent of its use in other psychiatric facilities and undertook a survey of other mental health centers. Using the September 1973 *Directory of Federally Funded Community Mental Health Centers* (12), we sent questionnaires to all community mental health centers in operation at the end of August 1974. We inquired about the adoption, acceptance, and advantages of POMR.[1]

Dr. Vickar is Instructor in Psychiatry and Dr. Herjanic is Associate Professor of Psychiatry, Washington University School of Medicine, 1420 Grattan St., St. Louis, Mo. 63104. Dr. Herjanic is also Assistant Superintendent, Malcolm Bliss Mental Health Center, St. Louis, Mo.

FINDINGS

Three hundred thirty-four questionnaires were sent out in August 1974; 158 (47%) were returned answered. Eleven replies had to be dropped from calculations because they were incomplete.

Thirty-six of the 147 centers (24%) were using POMR. These centers were apparently distributed randomly throughout the United States. Of these 36 centers, 19 used POMR for both inpatients and outpatients, 8 for inpatients only, and 9 for outpatients only. The average duration of use was about 12 months (1 center claimed to have been using a modified form of POMR for 27 years).

Thirty-four of the 147 centers (23%) planned to implement POMR, and 23 of the centers (16%) were uncertain. The remaining 54 centers (37%) had not considered using POMR.

Twenty-four of the 36 centers using POMR (67%) agreed that their use improved their record keeping in terms of organization, readability, and identification of problem areas. The better organization also made for easier supervision of residents and data collection for research purposes. When asked about improved patient care, the 36 respondents who were using POMR had mixed reactions, but 23 (64%) be-

[1]Copies of the questionnaire are available from Dr. Vickar on request.

lieved that patients benefited from the more consistent approach in documentation. Thirteen (36%) were not aware of a change in length of stay, but one respondent replied that length of stay increased because "people note [in the record] that [the] problem hasn't been resolved."

One of the interesting observations made by centers using POMR was that physicians were less favorably inclined to accept POMR than other members of the treatment teams. Only 9 of the 36 centers (25%) reported that the attending medical staff liked POMR. The replies expressed this through such comments as, "Approve in principle, frequently find it hard to change their own [physician's] way of doing things," "Are somewhat resistive," "It requires a higher level of medical acumen; this affects some staff who don't know what they are doing very well."

We wondered if the acceptance or rejection of POMR was related to the theoretical orientation of the institution. The 147 respondents indicated their treatment philosophy on a spectrum from purely psychoanalytic to predominantly physical therapies. There was no difference among groups with different theoretical orientations in terms of use of POMR. However, the more psychodynamically oriented centers expressed more difficulties in adapting POMR to their own use, e.g., "They produce stereotyped records that fail to yield dynamic appreciation of the patient's problems."

Aside from difficulties in adjusting individual therapeutic styles to a new system, many criticisms of POMR were directed at the extra clerical work involved, e.g.: "Some versions contain a great deal of information that may prove useless, and progress notes may require a good deal of paper shuffling." "The POMR require about twice as much writing by the doctors; we have enough trouble getting records written without doubling the work; what we need is a system that requires less writing."

DISCUSSION

After six months of using POMR on our inpatient service, our impression is that they do not add much in terms of actual patient care, despite the fact that they result in better organization of the records. Some people at Malcolm Bliss feel that POMR discourage charting because of their seemingly formalistic style, but the notes that are written within this system tend to be more complete and informative.

It appears that there is considerable interest among community mental health centers in problem-oriented medical records. One-half of the 147 centers who answered our questionnaire said they would be using this system by the end of 1975, and one-sixth were undecided. Even though one-third had no plans to introduce POMR, almost all requested the results of this survey, and many asked for practical references. With the increasing need for treatment evaluation and accountability (13), POMR may gain additional significance; they could become mandatory for all mental health centers.

Criticisms leveled at this system point out the difficulties individual therapists have in defining "problems." Obviously, the definition of a problem in psychiatry is a delicate task requiring a high degree of skill and experience. A considerable amount of reeducation and in-service training will be required to avoid overinclusion or particularization.

IN MEMORIAM

Malcolm J. Farrell
1906–1975

•

MALCOLM J. FARRELL, who died August 5, 1975, was a quiet, self-effacing man who devoted his life to improving the care of the mentally retarded. His ability to get things done led others to seek out this reluctant leader for the many top posts he filled so admirably.

We were friends throughout a lifetime, enjoying family picnics together as our children grew up, playing bridge on Sunday nights, and celebrating our wedding anniversaries on the same day. Mal and I were peers who shared the problems of running a state hospital. When he retired on April 4, 1974, he was feted at a testimonial dinner. Those who arranged the occasion knew how to please Dr. Farrell. Some 30 mentally retarded residents of the Fernald School were present and participated not just as guests but in the program as well. The major gift to Dr. Farrell was a check for a summer camp for residents of the school.

Born in Woburn, Mass., on May 7, 1906, Malcolm was the son of Joseph F. Farrell, who came to this country from Ireland to own and operate his own wholesale produce company, and of Elizabeth Thompson Farrell. Malcolm had a sister, Elizabeth (now Mrs. Spaulding of Needham, Mass.), and a brother, Robert, now living in Woburn.

When Malcolm was 14, his brother had an operation that miraculously restored him to health. Mal was so moved he vowed he would become a surgeon. Toward that goal Malcolm enrolled as a premedical student at Tufts University and stayed on course at Tufts Medical School until his fourth year, when a clerkship at Danvers State Hospital changed his career choice. After receiving his M.D. in 1931 and completing an internship at Boston's Long Island Hospital, he began what would now be a residency at Metropolitan State Hospital in Waltham, Mass. Six years later he accepted the post of assistant superintendent at the Walter E. Fernald State School. He was there about three years until World War II thrust him into a key post.

In February 1942 the Surgeon General of the Army established a separate Neuropsychiatry Branch and named Lt. Col. Patrick S. Madigan as its chief. On April 10 Capt. Malcolm J. Farrell was assigned as assistant to the chief in the developing branch. When Col. Madigan was transferred to the Adjutant General's office, the former superintendent of Metropolitan State Hospital, Col. Roy D. Halloran, was named to head the branch. Col. Halloran died suddenly on November 10, 1943 and Major Farrell acted as chief until Brig. Gen. William Menninger took command on Dec. 10, 1943.

Dr. Farrell planned and implemented the Army's neuropsychiatric hospital care system, the training of physicians in psychiatry, the assignment of psychiatrists to Army divisions, the adding of clinical psychologists and social workers to the treatment team, and the shaping of military medical policy. He wrote some of the key policy statements, lifted the blackout on neuropsychiatric matters and instituted an open press policy, and set standards for the transport of returning casualties and for the retention of personnel with neuropsychiatric disorders in the combat area for treatment. He was also involved in the refinement of diagnostic categories that led to the first edition of APA's *Diagnostic and Statistical Manual of Mental Disorders*. When the war ended Farrell was a full colonel and had been awarded the Legion of Merit for his outstanding contributions.

Farrell returned to the Fernald State School and served as its superintendent for the next 30 years. He had a master plan to build the best possible facility for the retarded, and his achievements remain for all to see in new buildings and high quality service, with teaching and research as integral parts. He inaugurated a work-release program, fostered and encouraged a parents' movement, extended the program of patient management into the community, combined education for students with vocational preparation, and established a prestigious research center. Fernald became widely known and Farrell recognized as a national expert on mental retardation whose opinions and advice were widely sought.

Shortly after World War II a group of ex-military officers met for an evening session at an APA annual meeting in Chicago. The Group for the Advancement of Psychiatry emerged out of the planning set in motion at that informal group session. The innovative notion of small groups of experts working intensively on a topic area with the aid of consultants from other disciplines has produced a series of prestigious reports. GAP also exercised enormous influence in reorganizing APA. Through the turbulent years of GAP's growth Dr. Farrell ran the fiscal and administrative affairs of the organization, serving as its secretary-treasurer from 1950 to 1969.

APA was also a major interest of Mal's. Besides serving on a number of committees, including the Committee on Certification of Mental Hospital Administrators (1958-61) and the Contract Survey Board (1962-73), he was especially active in District Branch activities and became Speaker of the Assembly of District Branches (1968-69). Dr. Farrell was attending the Assembly Executive Committee reception as

past speaker at the APA annual meeting in Hawaii when he collapsed and was flown home. It was the start of an illness (vasculitis and multiple strokes) from which he never recovered.

Dr. Farrell had many distinctions besides his GAP and APA activities: instructor at Tufts and at Boston University, bank director, and author of 68 scientific articles, mostly in the field of mental retardation.

Mal's family was very important to him. He met Virginia Corbin at a church meeting when they were teenagers; they were married on July 2, 1932. Two sons, Jay and Dudley, and his daughter, Ginny (now Mrs. Juan Blau of Panama), grew up in an extended family that gathered in friends and relations and shaped all in the Farrell moral mold.

Not seeking leadership, it sought him; avoiding the limelight, he illuminated his world. Dr. Farrell devoted much of his life to helping others and to the shaping of the institutions that serve the mentally afflicted. It is when we forget ourselves that we do things which are remembered.

WALTER E. BARTON, M.D.

LETTERS TO THE EDITOR

"Misleading" Concepts in Family Therapy

SIR: "Basic Concepts in Family Therapy: A Differential Comparison with Individual Treatment" by Leon Robinson, M.D. (October 1975 issue), is most misleading and perpetuates a polarized conception of family versus individual therapies. His basic assumption that "all individual therapies share a common perception of the nature and location of the forces most active in the formation of personality, the appearance of symptoms, and the production of change," including the beliefs that "intrapsychic events determine personality" and "changes in individual behavior are unopposed by environmental factors" is sheer nonsense. This paper perpetuates the silly either/or controversy of external versus internal determination of behavior, and its publication merely prolongs the sterile individual versus family therapy controversy (1).

Actually, most individual therapies, especially psychoanalysis, emphasize the impact of the environment on personality formation. In his first detailed case history (that of Dora), Freud noted,

> It follows from the nature of the facts which form the material of psychoanalysis that we are obliged to pay as much attention in our case histories to the purely human and social circumstances of our patients as to the somatic data and the symptoms of the disorder. Above all, our interest will be directed toward their family circumstances. (2, p. 18)

Why is there still such a reluctance in many settings to treat the family, despite the agreement of almost all theories of human behavior that family forces are among the critical determining variables in the development of personality and symptoms? The reasons for this reluctance would include the individualistic ethic of our culture, the greater practical difficulties in treating the family unit, the absence of an acceptable systematic theoretical framework for family therapy, the lack of any standard-setting association of family psychiatrists, and the as yet undeveloped mechanisms for third-party payments for this relatively new modality. This is most unfortunate, for family therapy holds special promise for the time-limited therapeutic interventions we are increasingly called upon to provide.

There is thus a responsibility for family therapists to evolve a meaningful theory, typology (3), and practice which will clarify those clinical situations most amenable to family treatment rather than continue to make puerile comparisons to the individual therapies.

F. M. SANDER, M.D.
Bronx, N.Y.

Dr. Robinson Replies

SIR: I can only conclude that the "silly either/or controversy" to which Dr. Sander refers is drawn more from his own prior thought and experience than from the contents of my article. The fact that he goes to the trouble of citing Freud in order to assert that my basic assumptions are lacking because they do not acknowledge the idea that most individual therapies "emphasize the impact of the environment on personality formation" suggests either a biased or inaccurate reading of my paper. I am led to this conclusion because I clearly stated in my article that "the importance of environmental factors in the shaping of personality is recognized by the individual therapies" (p. 1045).

As far as I can see, the major difference between my position on this subject and that of Dr. Sander has to do only with the question of emphasis. I take no either/or positions on family therapy versus individual therapy or on external versus internal determination of behavior. I believe, however, that while family therapy and the individual therapies do operate at shared levels of awareness regarding personality, symptom formation, and therapy, they also emphasize different aspects of these broad conceptual areas. This difference in emphasis is the basis of the ultimate difference in methodology. Dr. Sander's inference that "individual therapies, especially psychoanalysis" emphasize family and environmental factors as much as they emphasize intrapsychic events and cannot be differentially compared with family therapy at this level is poorly founded. His reference to Freud's case history of Dora does not offer much support for his contention because in that paper Freud stated in a footnote (1, p. 20) his belief that the principal causes of his patient's illness were a matter of heredity and constitutional predisposition. I do not see how this can be construed as an emphasis on the impact of environment.

I think the question of emphasis was well explained by Ackerman, who said, "Psychoanalytic treatment focuses on the internal manifestations of disorder of the individual personality. Family treatment focuses on the behavior disorders of a system of interacting personalities, the family group" (2). I concur with Ackerman that a discussion of differences is no cause to view the two approaches as "competitive or mutually exclusive."

I therefore cannot agree with Dr. Sander either in his denial of significant differences between family and individual therapy in their emphasis on environmental forces or in his

statement that attending to such differences stimulates only controversy. I submit that the differences in perspective I referred to in my article not only exist but are worthy of exploration and clarification as a means of facilitating communication concerning the shift in focus required when a person trained in the individual perspective wishes to work with families.

My personal experience in using this kind of comparative approach to introducing family therapy concepts to people who have previously worked only with individuals is that the comparisons are received as useful and do not tend to create controversy.

Philadelphia, Pa.

A Problem of Methodology?

SIR: I am writing to call attention to serious deficiencies in "Methylphenidate and Caffeine in the Treatment of Children with Minimal Brain Dysfunction" by Barry Garfinkel, M.D., and associates (July 1975 issue). These deficiencies are so serious, in fact, that our entire staff at the Ontario County Mental Health Center expressed surprise that the paper was published.

First, the study involved only eight children—hardly an adequate sample. Second (and even more crucial), the dosages of the drugs used were fixed at the same level for all of the children, and they were very low. It is abundantly clear to anyone who has worked extensively with drug treatment of children with minimal brain dysfunction that dosages must be carefully adjusted to fit the individual child. To anyone who has experimented with caffeine for these children, it is equally clear that a dosage of less than 200 mg/day is unlikely to produce worthwhile effects. At our clinic, we have used caffeine with a few children and have seen some good results at levels of approximately 400 mg/day. While our experience with caffeine has not been encouraging enough to lead to its replacing methylphenidate, pemoline, and *d*-amphetamine in our armamentarium, we have felt handicapped by the lack of any reliable work on dosage schedules for its use. The article in question—which has such a promising title—certainly does nothing to answer our questions.

ALLEN W. MARINER, M.D.
Canandaigua, N.Y.

Dr. Garfinkel and Associates Reply

SIR: Regarding the first issue raised by Dr. Mariner, the size of our sample, it is never easy to decide what constitutes an "adequate" sample. If the experimental control over the major variables is inclined to be weak, sample size usually needs to be fairly large. If the experimental control over major factors is strong, the sample size can be very small indeed. Workers in the tradition of radical behaviorism (operant conditioning) have, for example, long eschewed the use of formal statistics, preferring to show the power of variables by the effects they produce on the behavior of a single organism. While it is certainly the case that, in general, drugs are not so easy to manipulate as many environmental variables, it is frequently possible to demonstrate strong effects with relatively small samples. The fact that we were able to show a marked methylphenidate effect with a sample of eight children merely confirms this point. Sample size in itself is, however, not the real issue. If the investigator opts for a small-sample design, he should be prepared to present a reasonably fine grain of data analysis. In such cases, the reader is perhaps entitled to know how the drug or other variable affected each individual subject. This issue, we sense, is the real basis of Dr. Mariner's objection; fortunately it is one we can answer.

We had in fact anticipated this objection. On page 725 of our paper, we devoted a short paragraph to the importance of the effects of the drugs on the performance of individual children. We stated,

> While the overall statistical analysis gives the main important trends, it is interesting to note that individual children demonstrated both a dramatic therapeutic response to methylphenidate and a pharmacological effect from caffeine, although the latter was not as marked.

In our original version of the paper, we had included some sample data drawn from individual children. While it was not possible to include these data in the published version due to space limitations, individual records rather than formal statistical analysis are available in another publication (1). It is good to be able to turn a "serious objection" into an opportunity to provide a colleague with the detailed information he requires.

Dr. Mariner's second objection, that we did not adjust the dosage to fit each individual child, is easy to understand in principle; however, it makes little impact in practice. He is perfectly correct to point out that fixed-dosage studies are inherently weak, especially when dosages have not been adjusted to fit each individual child. It would indeed have been better had we adjusted the dosage level to fit each child, but this would have added considerably to the administrative complexity of the study. Since the children's weights ranged from 72 to 80 pounds, we can hardly be criticized too strongly for not adjusting the dose.

We feel that the use of a single dosage is the only objection possibly meriting the adjective "serious." Again, we anticipated this objection by pointing out the need for exploring the effects of varying doses of caffeine. Obviously, it is much better to vary dosage systematically than to use a single level. However, it is often impossible to accommodate all the niceties of experimental design within a single study. Schnackenberg's article (2) was valuable because it pointed out an important observation: our study is an improvement on Schnackenberg's but is not methodologically perfect. Our latest study, which examines dose-effect relations of caffeine in children with minimal brain dysfunction, is more advanced in design than the study Dr. Mariner refers to. This double-blind crossover study analyzed behavioral changes in response to 150 mg and 300 mg of caffeine alone and in combination with a fixed dosage of methylphenidate. (Prelim-

inary analysis of our results has been completed and a manuscript will soon be submitted for publication.)

If Dr. Mariner's criticism spurs us or others on to attempt further studies, it will have been well placed.

The Need for Insect Sting Kits

SIR: I am engaged in what seems at times to be a one-man crusade. As an allergist, I am acutely aware of the life-or-death situations that can be created by insect stings. I have run into several cases where death could have been prevented if an emergency insect sting kit had been available.

We physicians give insect sting kits to patients who need them, and we train them in their use. Yet people in positions of responsibility—school nurses or principals, forest rangers, Scout masters, and others who may encounter people in allergic shock—do not have the kits, nor do they know how to use them. Most state laws prohibit sales of such kits without prescription. I think state laws should be changed so that persons in the kinds of positions I have listed above, after receiving appropriate training, could purchase the kits without prescription. I hope others feel likewise and will be motivated to write their legislators to change the laws.

I would also appreciate hearing from other doctors who know of cases where the use of an insect sting kit would have prevented death.

Diagnosis and Treatment in a Case of Tardive Dyskinesia

SIR: In "Deanol in the Treatment of Tardive Dyskinesia" (August 1975 issue), Daniel E. Casey, M.D., and Duane Denney, M.D., appear to have adequately documented that their patient had this disorder. What is unclear, however, is whether this man was initially diagnosed correctly, i.e., did he have schizophrenia? There are several reasons to doubt this diagnosis. First, he was described as being without psychiatric history until 1968, when we surmise he would have been 54 years old; such a late onset is uncommon in schizophrenia and would be more likely to indicate a depressive illness. Second, he was described as "mildly despondent . . . agitated . . . mood was depressed . . . affective responses were appropriate . . . no evidence of thought disorder." Thus there appear to be positive findings of depressive illness and no evidence of schizophrenia. Third, his initial presenting symptoms are described as "social withdrawal, agitation, and inability to think clearly." These complaints are not pathognomonic of schizophrenia by any means but could be accounted for by a severe depression.

Even if this patient was correctly diagnosed as having schizophrenia, a number of questions remain about his course of treatment. He was treated with a combination of chlorpromazine and trifluoperazine; there is no proven benefit of such a combination (1). The course of medication was continued over a long period of time (5 years or so) without apparent attention having been given to drug holidays or discontinuance until the authors assumed his care. This is difficult to understand given the historical information in the article itself and current guidelines for psychopharmacology (2, 3).

In essence, our concern is with the inadequate application of diagnostic criteria and a cogent treatment plan. One would hope that such positive steps would lower the incidence of neuroleptic-induced disorders and obviate the need for experimental pharmacotherapy, i.e., prevent the condition rather than treat it.

A final point regarding the proposed presence of an antagonistic cholinergic mechanism in the nigrostriatal pathways: if deanol, an acetylcholine precursor, improved the patient's condition, how does one account for the failure of anticholinergic drugs to worsen his neurological condition?

ROBERT A. KUWIK, M.D.
MELVIN J. STEINHART, M.D.
Albany, N.Y.

Drs. Casey and Denney Reply

SIR: The inquiry of Drs. Kuwik and Steinhart primarily addresses basic issues in patient care. We heartily agree that it is imperative to apply diagnostic criteria critically and to formulate a treatment plan based on indicated therapeutic guidelines appropriate to the diagnosis. Although we have the benefit of hindsight, our clinical impression was also that of an affective disorder rather than schizophrenia. Unfortunately, our clinical contact with this patient began in 1973, and his neurological complication was discovered in the course of diagnostic evaluation directed to the very issues raised by Drs. Kuwik and Steinhart.

Prevention of tardive dyskinesia is a primary responsibility of each physician. Currently, we advocate using neuroleptic drugs only for indicated conditions, at the lowest effective dose, with periodic reassessments, and with drug holidays whenever possible. In spite of these efforts, some patients will develop tardive dyskinesia. At an appropriate time, a candid discussion with the patient and the family regarding the risks and benefits of pharmacotherapy may assist

in the management of this unfortunate condition.

The role of cholinergic mechanisms in tardive dyskinesia is not completely understood. The proposed balance between dopaminergic and cholinergic influences implies that excesses or deficits in either could effect a change in the clinical condition. While deanol in large doses benefitted this particular patient, the anticholinergic agent was apparently insufficient to aggravate the dyskinesia. There are inadequate pharmacokinetic data to account for the variations seen in the response of patients with tardive dyskinesia to a variety of cholinergic and dopaminergic agonists and antagonists. Indeed, the "balance hypothesis" itself must be considered tentative at this point.

We hope that further research will lead to both treatment and preventive strategies for this unfortunate iatrogenic disorder.

DANIEL E. CASEY, M.D.
Providence, R.I.
DUANE DENNEY, M.D.
Portland, Ore.

Semantics and Psychiatry

SIR: I enjoyed "Affect, Mood, Emotion, and Feeling: Semantic Considerations" by Richard Ketai, M.D. (November 1975 issue). It represents a much needed attempt at clarifying these terms more precisely and pointing out some of the ambiguities in their current usage. I have no major argument with the author's commendable concluding remarks and the potential usefulness of his proposed classification, but I would like to make a few comments.

Obviously, as the title of the article clearly implies, Dr. Ketai chose to treat his subject explicitly and selectively on a semantically inspired, descriptive-phenomenological level rather than focusing more specifically on the terms' underlying neurophysiological bases and related conceptual considerations. The latter considerations, however, may be just as important as the former or even more so.

In analyzing the meaning of a word, it is always a good idea to go back to its original semantic root (usually Greek or Latin), as this more often than not represents the percolated cognitive wisdom and condensed perceptions of many antecedent generations. The term "affect," for instance, comes from the Latin *afficere*, "to do something to, exert influence on"—which is exactly what the "affect" does through its various physiological substrates and functional components within the respective parts of the thalamus and the limbic system as these influence, pervade, and *affect* in varying degrees subsequent emotional and behavioral responses of a higher phylogenetic order. In this frame of reference, the more primitive, instinctually overriding, id-related nature of the affect is also illustrated by its enhancement, lack, or depletion in such (biochemically determined?) disorders as manic-depressive illness, schizophrenia, and severe endogenous depression. In these disorders, the patient's affectivity and its pathology becomes much more an issue of medical-clinical understanding than of semantic definition.

Similar consideration—although perhaps to a less primarily "biological" degree—can be applied to the emotions and their psychophysiological accompaniments, as well as their practical implications for the practice of psychosomatic medicine. Mood and feeling, on the other hand, are, I believe, much more closely linked to higher cortical functions, which makes them more specifically human phenomena (and therefore part of the general human condition) as to their psychological and psychopathological nature and propensities.

In saying all this, I am conscious of partially disregarding or even neglecting some analytic formulations and theoretical definitions such as those quoted by Dr. Ketai; I am also quite certain that Dr. Ketai, as a practicing clinician, is well aware of these implicit aspects of his topic. However, they seem worth mentioning and emphasizing because in psychiatry we often tend to get caught up in semantics, arguing about words and descriptive terminology rather than focusing our attention on scientifically documented facts and on scrutinizing the validity of our concepts and theoretical formulations.

F. PAUL KOSBAB, M.D.
Northport, N.Y.

Dr. Ketai Replies

SIR: There seems to be little disagreement between Dr. Kosbab and myself about the subject of affectivity. His discussion of affect, mood, emotion, and feeling does not contradict the outlined categorization presented in my article. Certainly, mood and feeling may, among other things, be considered specifically human phenomena, and affect (affective sensations, to be precise) may be seen as a more primitive stimulus for higher order behavior. These descriptions are not inconsistent with my proposed classification, which is based on temporality, subjective-objective perspectives, and distinctions between what exists and how it manifests.

Dr. Kosbab correctly points out that labeling something does not necessarily ensure that we will understand it better. In psychiatry, we are particularly guilty of obscuring understanding with words, especially through the use of jargon.

As far as I am aware, the only ways human beings have to communicate are through words, including the affective display behind spoken words, and body language. Communication by ESP is unproven or at least debatable. Imperfect as words may be, we must depend on them to augment communication and understanding. Without them, Dr. Kosbab and I would not be having this dialogue.

Therefore, to keep communication as unmuddled as possible, words must be used precisely. This requires definitions and distinctions, which was the purpose of my article. I agree with Dr. Kosbab that words should not be reified or substituted for understanding of concepts. Semantic agreement is necessary, however, to begin to communicate better and, eventually, to lead to understanding.

RICHARD KETAI, M.D.
Ann Arbor, Mich.

A White-Coated Tale

SIR: There has been a great deal of debate in recent psychoanalytic literature regarding certain strictly technical fine points in the analytic method. A recent article in that bastion of psychologic know-how, *The New Yorker*, raised the issue of the use of the analytic napkin. Other issues raised include

the choice of pipe versus cigar in the psychoanalytic hour, the bow tie versus the straight knotted tie, and the psychoanalyst's day off, which has, since Freud's time, traditionally been Thursday. Nowhere in the literature, however, has anyone addressed the question of whether or not a psychiatrist should wear a white coat while doing therapy.

We know that in his early years, Freud wore a long white laboratory coat in his consulting room. Only in his middle and late years did he begin wearing a three-piece suit. Since Freud never wrote about this issue, we are left in the dark as to what we psychiatrists should wear. In researching this sartorial issue, I chanced upon a plausible answer to the question, and I am pleased to be able to share it with you.

Having traveled to New York City recently to attend a psychodrama convention and finding myself arbitrarily thrown out for supposed lack of dramatic skill, I found myself wandering in the rain on Manhattan's Lower East Side. At the suggestion of one of my supervisors, I had thought to have cuffs put on a pair of old tweed pants. When I happened upon a small tailor shop, I decided to grab the moment and go in. The tailor was a wise-looking Jew in his mid-eighties. As he worked, we made conversation over the tea and *schnecken* he kindly provided, and I soon found out that he was born in Vienna. I asked him if he had known Freud, and to my utter amazement and good fortune, he said that not only had he known Freud but had been his personal tailor.

Here at last was my opportunity to answer the burning question that so often plagued me. I wasted no time and asked him immediately about Freud's having changed from the white coat of his early years to a three-piece suit. The tailor told me the following tale, which he swore to be the truth.

Apparently, in his early years of practice Freud was considered quite a fashionable dresser in Viennese circles (as a matter of fact, he was twice voted the best dressed analyst in Vienna by the Viennese Analytic Society). The tailor said that the Professor had a penchant for silk shirts, wide wale corduroy pants, long waistcoats, and fur-trimmed overcoats, all of which the tailor made personally. The tailor was also occasionally asked to reweave a hole in one of Freud's white coats; he said that although Freud was a brilliant thinker, he was sometimes absent-minded and put a lit cigar in his pocket. In any case, Freud never wore three-piece suits in the consulting room.

One fine spring day in the last part of the nineteenth century (the tailor could not be more specific), Freud entered the tailor's shop and demanded his full attention. He said that he had decided to purchase a whole new wardrobe for use only in his work. He was through with white coats in the consultation room. Instead, he wanted a dozen three-piece suits made from the finest material to be found, and he stated that the vests must be multicolored. He said he would return in one week to claim his new wardrobe.

The tailor was, as you can imagine, flabbergasted—he had known Mrs. Freud to be somewhat fickle in her taste for fashion, but never the Professor. "These psychiatrists," the tailor thought out loud, "they're all *meshugah*." What could have brought about such a drastic change in haberdashery style? The tailor, being somewhat of an amateur psychologist himself, as well as subscribing to the Austrian edition of *Psychology Today*, thought he knew the answer. Freud, he reasoned (without any particular logic), must be going through his change of life. He resolved to ask Freud about this at their next meeting.

When Freud appeared a week later, the tailor said, "Well, Sigmund, I have known you 10 years now. You are a good dresser. Never have you worn a three-piece suit in the analytic hour—only Victorians wear three-piece suits." Freud responded with a question of his own—as he so often did. He asked the tailor if he read the Bible. The tailor said that unfortunately he had no time for religion, but he remembered a little from his 5 years of Hebrew school as a child. "So," said Freud, "you surely know the story of Joseph and his multicolored vest." Freud then explained how, while doing research for his book *Moses and Monotheism*, he had chanced upon the story of Joseph. Joseph's claim to fame, as you will recall, was his prowess as an interpreter of dreams. He far surpassed the local class of soothsayers, magicians, and wise men. He was often seen around Canaan dressed in a marvelous multicolored vest given him by his father.

From the tailor's description, it appears that after reading about Joseph and his fame as a dream interpreter, Freud gave up his identification with Moses and, along with it, his idea that he was destined to climb the Matterhorn, dressed in a white robe, to receive a set of Ten New Commandments from God. Instead, he formed an intense identification with Joseph, whom he had displaced as the most famous dream interpreter in over three millenia. From that time on, Freud never wore a white coat, but was instead seen in the most stylish of multicolored vests. This is why strict Freudian analysts today no longer wear white coats, but rather three-piece suits with multicolored vests.

LETTERS TO THE EDITOR are welcomed and will be published, if found suitable, as space permits. Like other material submitted for publication, they must be typewritten double-spaced. Letters should not exceed 500 words, including references, unless a special arrangement has been made with the Editor, and they will be subject to the usual editing. Receipt of letters will not ordinarily be acknowledged.

BOOK REVIEWS

The Working Brain: An Introduction to Neuropsychology, *by A.R. Luria; translated by Basil Haigh. New York, N.Y., Basic Books, 1974, 371 pp., $12.50.*

Luria's Neuropsychological Investigation: Text, Manual, and Test Cards, *by Anne-Lise Christensen. New York, N.Y., Spectrum Publications (Halsted Press, John Wiley & Sons, distributor), 1975, text: 203 pp., $24.00 (paper); manual: 55 pp., $7.95 (paper); test cards: 4 sets, $40.00.*

Prof. Aleksandr Romanovich Luria is one of the U.S.S.R.'s most distinguished scientists; his pioneer studies of brain function have earned him worldwide acclaim. He is a member of the Academy of Pedagogical Science of the U.S.S.R. and a foreign associate member of the U.S. National Academy of Science and the U.S. National Academy of Education.

Fortunately Luria's most important writings have been published in English: *Traumatic Aphasia* (1), *Restoration of Function After Brain Injury* (2), *The Role of Speech in Regulation of Normal and Abnormal Behaviour* (3), *Higher Cortical Functions in Man* (4), *Human Brain and Psychological Processes* (5), *The Mind of a Mnemonist* (6), and *The Man with a Shattered World* (7).

The title *The Working Brain* is well chosen. Luria attempts in this book to correlate cortical structure and function according to a unitary thesis. Despite the brain's architectural complexity and the differences among its individual systems, the brain's functions (its "works") are not localized. Rather, they are distributed in broader areas. The contribution of each cortical zone to the whole organization is very specific. Consequently, the behavioral effect produced by each zone is very specific. Therefore, a qualitative neuropsychological analysis must be performed to assess the impairment of cerebral function.

A detailed description of the neuropsychological techniques used by Luria and his collaborators at the Burdenko Neurosurgical Institute in Moscow is available in the work of Anne-Lise Christensen, a Danish clinical psychologist. Her English version of Luria's text is composed of three parts. The first is Luria's own summary of the functional rationale he has developed to specify the "qualification of the [brain] defect" over the last 40 years. The second part describes and illustrates the details of the test procedures used by Luria and associates to examine motor, acoustico-motor, cutaneous, kinesthetic, and visual functions. Tests for the examination of speech, writing, and arithmetic skill as well as mnemonic and intellectual processes are also described. The third part of the text consists of thumbnail sketches of patients whose functional impairments demonstrate various brain lesions. Christensen also provides a manual that contains typical test wordings that are used to elicit responses to a set of cards and pictures. The test cards are also available in a plastic box.

In his conclusion to *The Working Brain* Luria echoes the point he and other contributors to the growing science of neuropsychology have repeatedly stressed: the analysis of psychological processes relies on a qualitative empirical approach that adduces correlations of function with structure.

Although it is becoming progressively more difficult to keep abreast of the burgeonings in all of the disciplines that have multisected the study of human behavior, seminal summaries such as *The Working Brain* are recommended for those of us who struggle to attain the accolade of compleat psychiatrist.

Ganja in Jamaica: A Medical Anthropological Study of Chronic Marihuana Use, *by Vera Rubin and Lambros Comitas. The Hague, The Netherlands, Mouton (Scotch Plains, N.J., Mouton/Macfarland, distributor), 1975, 205 pp., $9.95.*

This is one of the most interesting, reliable, and comprehensive studies of the complex relationships involved in the use of cannabis that has yet been published. It is the result of a study sponsored by the Research Institute for the Study of Man in collaboration with the University of the West Indies and supported by the National Institute of Mental Health. The project took 18 months to complete and a large proportion of the time of 45 staff members and consultants.

It is quite probable that cannabis (or "ganja," as it is called in Jamaica) is used with greater intensity in Jamaica than anywhere else in the world, certainly in the Western hemisphere. An extensive study of 30 ganja smokers and 30 nonsmokers, all of whom were working class native men, revealed no significant differences between the two groups. There was also little correlation between the use of ganja and crime. The effects of ganja smoking on the lung's function were thought to be similar to those of tobacco smoking. The incidence of alcoholism was found to be quite low among ganja smokers, supporting the benevolent alternative theory.

The general findings and conclusions of this study are consistent with those of the Indian Hemp Commission in 1893, the LaGuardia Committee of the New York Academy of Medicine in 1944, the LeDain Commission of Canada in 1973, and the National Commission on Marihuana and Drug Abuse of the United States in 1972.

It now seems apparent that the facts to support more rational attitudes toward marijuana are plentiful; what remains is the development of social policies that will not harm users of the drug more than the drug itself does.

This volume is highly recommended to anyone who wants to get an accurate picture of the nature of the effects of marijuana on human beings as well as its role in social and cultural interactions.

DANA L. FARNSWORTH, M.D.
Boston, Mass.

On Not Knowing How To Live, *by Allen Wheelis. New York, N.Y., Harper & Row, 1975, 114 pp., $5.95.*

It is hard to categorize this slim volume. Possibly it fits best into the genre of obiter dicta, a genre that was prevalent in the last century but is now nearly extinct. An amalgam of philosophical reflection, literary comment, and narrative vignettes (whether fictional, autobiographical, or a mixture of both is not always clear), this brief text might have been transcribed from the author's private journal-cum-commonplace book. As such it is an intensely personal document. Indeed, at times, one feels as if one were listening to free associations from the couch—except that free associations rarely come with such polish.

Wheelis writes well, his prose not infrequently bordering on the poetic in phrasing and imagery that evoke a resonating chord of recognition in the reader. Only rarely does he come close to the shoals of sentimentality—a danger that particularly awaits the author who sails the seas of Weltschmerz. In a manner often reminiscent of Amiel, Wheelis writes sensitively and affectingly of the unfulfilled promises of youth and the sad ironies of human life and love. This is in many ways a melancholy book, but an honest one. It should find a sympathetic ear in those who are introspective by profession or inclination.

Five Lives at Harvard: Personality Change During College, *by Stanley H. King. Cambridge, Mass., Harvard University Press, 1973, 219 pp., $7.95.*

Five Lives at Harvard is the first book to be published as a result of the Harvard student study, a major longitudinal study of personality development during late adolescence and early adulthood. The complexity of this interdisciplinary research (the research team consisted of representatives from sociology, statistics, clinical psychology, social psychology, psychiatry, and psychoanalysis) is reflected in the four objectives: 1) investigation of the process of personality change and stability as this is related to personality structure and interaction with the college, 2) study of the socializing and allocating functions of the college as an organization in society, 3) development of research methods and general research strategies, and 4) development of theory. This last objective is particularly important. According to King, the study was unable to proceed on the basis of hypothesis testing based on well-established theory because such theory did not exist.

As a report of one phase of the Harvard student study, this book makes a number of significant contributions methodologically, through an unusually thorough application of the clinical method; theoretically, through an explication of the applicability of a number of developmental constructs to the course of late adolescent and early adult growth processes; and empirically, as the basic findings provide important evidence in support of the "continuity" model of growth.

In light of the researchers' extensive reliance on the clinical method, their choice of a particular theory as a framework for analysis is particularly important. The team drew upon psychoanalytic theory, beginning with Freud's exposition of ego psychology and continuing with subsequent elaborations of adaptive aspects of ego functioning.

King and his colleagues came to two major conclusions in terms of the adaptation constructs. First, they found that individuals in this age group differed in "adaptive sense": some students seemed to know better where they were going and how "behavior at one life phase will mesh with behavior at a later life phase." A second conclusion was that students showed more instances of successful adaptation, as King defined it, as they progressed from their freshman to their senior year.

This general theoretical set of ego psychology and adaptation led directly to a consideration of the competing "crisis" and "continuity" models of development. In an important contribution to the understanding of how the crisis model relates to late adolescent development, King distinguishes four variations of the crisis model, two of which involve a new integration and can lead to adaptation. He identifies the first and most dramatic as that of upheaval and fragmentation, followed by reorganization on a new level. With recovery from the crisis comes a more realistic self-appraisal. In the second variation, disruption is followed by reorganization on a new level, but it is attained only slowly and painstakingly. King notes, "The person moves ahead in some areas, then seems to lose ground again for awhile. Change may be slow to appear and some years may go by before the reorganization is complete" (p. 30). The "sophomore slump" and the "identity crisis" are popularized versions of this second variation of the crisis model.

A third variation occurs when disruption and upheaval do not lead to a reintegration at a new level but cause a return to some kind or level of personality organization that existed before the crisis occurred. The person may go from crisis to crisis with minimal if any developmental change. King indicates that the common parlance for this variation is "perpetual adolescent."

The fourth variation occurs when the crisis is followed by regression and deterioration. Psychopathology is usually severe in this instance. College can awaken old unresolved issues; a relatively minor problem can become the basis for a major crisis. King states that only a few students in the study were in this category.

The following key findings of the Harvard student study bear directly on the crisis model versus the continuity model:

1. The majority of the students in the sample gave no evidence of having experienced the disruption and turmoil characteristic of the adolescent crisis. King notes that most students did not "feel" that they had gone through crisis (p. 32).

2. King states, "Significant growth occurs more frequently

through finding new applications for successful behavior patterns from the past, through increasing the repertoire of responses, and through modifying and reworking patterns from the past to meet new situations" (p. 32). Thus growth is likely to be unobtrusive in nature because it occurs through a series of small changes.

3. Growth occurs when a person learns how to transfer effective automatic patterns of the past to new situations, a pattern that King calls "growth by extension." In this pattern, common features of quite different situations are recognized (p. 33).

4. Growth occurs when responses that are based on successful experiences from the past are changed to fit the characteristics of new situations. This "growth by modification" pattern is an important sharpening or focusing process in that a person gets deeply involved with something and discovers new ideas and interests or reworks old values as guidelines for present conduct (p. 33).

5. The final pattern identified is "growth by accretion and exploration," in which growth occurs by the "development of new patterns of behavior related only indirectly to material from the past, but in the indirectness there is continuity" (p. 34).

There are a number of important implications of the work of King and associates. If we assume that the continuity model is the basic model of growth in college students, this fact has major unexplored implications for modification of the college experience. What are the curricular implications of growth by extension, growth by modification, and growth by accretion and exploration? What college environments will best facilitate what types of growth? What are the implications for the out-of-class learning environment of a college?

King and associates have completed a pioneering project. Its implications have just begun to be explored. The book is a must for all who are interested in the nature of late adolescent and early adult development and in the learning environments of colleges.

Gesell and Amatruda's Developmental Diagnosis: The Evaluation and Management of Normal and Abnormal Neuropsychologic Development in Infancy and Early Childhood, 3rd ed., *edited by Hilda Knobloch, M.D., and Benjamin Pasamanick, M.D., New York, N.Y., Harper & Row, 1974, 514 pp., $14.95.*

Through the efforts of two of their former students, the legacy of Arnold Gesell and Catherine Amatruda is embodied in this new edition of their classic work on developmental diagnosis.

The appearance of the third edition 25 years after the second signifies the durability of the Yale Child Study Center's early productivity as well as the relative lack of clinically useful advances in the field of child development research. An even more telling point is made by the editors when they point out, "In spite of the lip service that has been paid to the importance of development, there has been little advance in its practical incorporation into pediatric training and practice."

This volume represents a truly new edition with both additions and revisions in content. Not only is the scope of child development extended to preconception, but the developmental norms have been continued through the fourth and fifth years of life. Of particular interest is the inclusion of data validating the criteria employed at each age level. The current utility of the Gesell scales is substantiated by high reliability in administration and by a clinically significant level of predictability. A shift in attitude toward children with mental handicaps is reflected by the replacement of such terms as "brain injury" by "brain dysfunction" and "amentia" by "mental subnormality."

The bias of Gesell's work is reflected through the exclusive focus of the book on child-centered diagnostic procedures. His caveat that psychodynamic formulations have been overemphasized in developmental work is reflected in the philosophy of the editors. Although mentioned in passing, critical interpersonal transactions between parents (particularly the mother) and child are ignored. The young child is still regarded as a self-contained unit rather than an individuating organism. The stance of the book also perpetuates a distinction between heredity and environment without recognition of the influence of function on the structure of the central nervous system. A further difficulty is the lack of inclusion of the growing body of knowledge regarding individual differences. Pasamanick's continuum of reproductive casualty, although useful, continues the viewpoint that deviance in behavior is based on chronic organic brain disorder and not on individual variations.

Perhaps the most significant flaw in this volume is the unchanged attitude toward the clinical aspects of adoption. Although a one-year probationary period before the finalization of adoption is appropriately advised, the concept of boarding foster care in order to ensure a developmental diagnostic study before placement of the infant is perpetuated. Ignored in the process is the infant's need for early placement in a stable caretaking home.

Of great value is a revised and practical developmental screening inventory for use with children between the ages of 4 weeks and 18 months as a means of recording the developmental progress of children in pediatric practice.

The third edition of *Developmental Diagnosis* remains a necessity for those engaged in the primary care of infants and a useful orientation to developmental diagnosis for the child psychiatry trainee. As an easily read, coherently organized, and thorough treatment of the neurobehavioral development of the young child, it deserves a place in the libraries of all professionals dealing with young children.

Going Sane: An Introduction to Feeling Therapy, *by Joseph Hart, Ph.D., Richard Corriere, Ph.D., and Jerry Binder, M.A. New York, N.Y., Jason Aronson, 1975, 464 pp., $12.50.*

The distinguished semanticist H. Dumpty once observed, "When *I* use a word, it means just what I choose it to mean—neither more nor less." The reader of this book, an introduction to feeling therapy, must keep this principle in mind and recognize that the authors have chosen to have a number of familiar words mean something other than what most of us usually mean by them.

For example: "Insanity is living with less. It is the way most people live, but seldom recognize." It is also "merely stopping oneself from being." Bedwetting, overeating, chronic smoking, homosexuality, and depression (among other conditions) are points on a continuum between com-

plete and incomplete feeling. They are fictitious ailments created by labeling, because there is "only one ailment and it is insanity—living from incomplete mixed up feelings."

To rid oneself of reasonable insanity one might seek a therapy that is "not just another theory or a new set of techniques, but a way of life," and "since 'therapy' is taking care of oneself, it makes no sense to ask that a human being would ever want to stop taking care of himself."

Feeling therapy is more nearly akin to R.D. Laing's antipsychiatry than to any other mode of treatment. It is a long-term process that begins with actively encouraged abreaction and ends with integration and transformation. The authors believe, probably correctly, that one could not apply their feeling exercises and techniques outside the total context of feeling therapy as a part of an eclectic method. They also emphasize that "Feeling Therapy is not a technique or a theory; it is a community. When the techniques are practiced without the community they will not have the same effects." Feeling therapy is described as a community in which the therapists live and work together; patients who join this community live and work wherever they want within the particular city. In this community and in this context therapists are patients and patients become therapists.

Among the most interesting features of this book are the lengthy transcriptions of therapeutic interviews. Unfortunately, one has little information about the individuals interviewed or their problems beyond the facts that emerge in the interviews themselves.

This book is addressed to the general public as well as to professionals; it is meant to give an overview of feeling therapy. The academic reader who desires data or "proof" is referred to the authors' research articles and monographs.

People who want feeling therapy will find instructions for applying for it in the appendix. One must submit an autobiography and take a number of psychological tests. Sometimes conditions are set for entering this therapy; for example, a woman who wrote that she desired therapy for obesity (lifelong) was told that she would be accepted as soon as she lost 30 pounds.

If one wishes to become a feeling therapist, he or she may apply for a residency training program. This use of the term "residency" may reflect the influence of the medical model or may merely be a manifestation of the authors' tendency to "use clinical words because they evoke beliefs about us and what we do." At any rate the program is open to professionals and paraprofessionals who have completed at least one year of therapy at the feeling therapy center. Community training programs are open to groups of professionals who want to start their own therapeutic communities.

MERRILL T. EATON, M.D.
Omaha, Neb.

Mental Deficiency: The Changing Outlook, 3rd ed., *edited by Ann M. Clarke and A.D.B. Clarke. New York, N.Y., Free Press (Macmillan Publishing Co.), 1975, 856 pp., $25.00.*

The introduction to the first edition of this book stated,

> When action is taken to deal with the medical and social aspects of a particular disability, not only is the lot of those who suffer from it improved, but added knowledge makes possible more effective preventive measures. There is no reason to doubt that this will also happen in mental deficiency.

The publication of this third edition, 16 years after the first, validates the accuracy of that prophecy and verifies the appropriateness of the title *The Changing Outlook*.

An attempt to secure a copy of the second edition was invariably met with, "Sorry, on loan, may we place your name on the waiting list?" I think that alone is testimony to the popularity and usefulness of this volume and makes it easy to predict that this third edition will meet with equal if not more acclaim.

The physical makeup of the book has shown growth and change—the pages are larger and have increased in number from 513 to 856. For some reason—design, style, print, or whatever—the third edition seems much easier to read than the first. The number of contributors has been increased, reflecting the growth of basic information and the interest and involvement of such ancillary disciplines as genetics. What seems noteworthy is the similarity in presentations from a more or less diverse group of contributors. The content hangs together as a unit and not as an uneven collection of essays, as is so often the case in books by many authors. Although there have been vast and even dramatic changes from the first to the third edition; such as the relegation of words like "idiot," "imbecile," and "moron" to obsolescence, the language remains terse, lucid, economical, and at times witty, which places this book above dull pedantry.

The list of contributors lends argument to those who would point a finger at psychiatry for having abandoned the field of mental retardation, an argument that has little validity today when one views the broad spectrum of disciplines that now comprise the area of mental retardation. The book encompasses areas of knowledge ranging from neonatology to parental psychology to governmental involvement and responsibility.

The book's approach to this very broad field is not based on the medical model. It is more directed toward mental deficiency as a "social concept with fluctuating thresholds of community tolerance." In the chapter on cerebral palsy, for example, the following statement is made:

> No attempt has been made to cover the strictly medical aspects of cerebral palsy or to consider the literature of the ancillary medical services such as physiotherapy, occupational therapy and speech therapy.

This kind of approach does not necessarily detract from the content; it emphasizes another approach that physicians might find informative and useful.

Along with the experiences, research results, and ideas of the respective authors there is a very extensive compilation of pertinent literature—I would guess there are no less than 1,500 references in the collected essays. The material is presented in a manner that gives the novice a broad but clear perspective of the field of mental retardation. Equally important, the more sophisticated reader is presented with conflicting arguments and hypotheses to stimulate further questions and thought. The beginner will note the important landmarks and hilltops as well as the clear plains and valleys. The researcher will find directions indicated toward unexplored areas as well as a description of the swamplands, crevasses, and wasteful whirlpools.

Perhaps human psychodynamics does not lend itself readily to categorization and statistical interpretation. For this reason the chapter on "The Effect of the Severely Subnormal on Their Families" was the least satisfactory for therapeutic purposes. There are quotations, references, statistics, and descriptions of socioeconomic factors, but there is

little if any mention of the human tragedy and emotional impact of mental retardation on the individuals or on intrafamilial relationships. Statistics and percentages are of no import to the affected individuals; I was disappointed at the paucity of depth psychology. References are made to papers on "shame and guilt of parents," but there is little discussion of what this means or how it might be of therapeutic service. No mention was made of the various manifestations of denial as the generally accepted most common defense mechanism employed by parents.

I strongly believe that this volume will be most helpful to a broad audience interested in the changing outlook in the field of retardation. Altogether, it is a handsome, helpful, encompassing volume that brings unity to and strengthens the structure of the body of knowledge concerned with mental retardation. Decidedly, it refines the boundaries of this emerging discipline.

JOSEPH MICHAELS, M.D.
New York, N.Y.

Thinking About Crime, *by James Q. Wilson. New York, N.Y., Basic Books, 1975, 221 pp., $10.00.*

This is an unusual book. It grasps the unwieldy subject of crime; it attacks some common attitudes toward crime among the public, the law-enforcement agencies, and the courts; it pricks the bubble of rehabilitative hopes; and then it enters the fog of "public policy." This book can best be described as a clearheaded critic's view of the amorphous and often befogged universe of crime from the vantage point of an expert on government rather than psychiatry or sociology (the author is Henry Lee Shattuck Professor of Government at Harvard University). It is remarkable in that no special school is advanced, no special theories invoked, and no panaceas offered—only a thorough analysis of the myths and practices surrounding crime in the United States.

Professor Wilson explores the increasing crime rates of the 1960s because that was the decade of the emergence of almost universal drug use. It also witnessed the emergence of what Wilson terms a "broad national force" of unknown nature that stimulated the reported rise in crime. The author's method is to study how the community, the police, politicians, criminologists, psychiatrists, and the courts look at and treat crime as well as their underlying attitudes toward crime.

Wilson zeroes in on the problem of crime causation (or, more accurately, the presupposition of causation). Many eminent sociologists have insisted that we first find the "cause of crime" and then develop a program of action from this discovery, whereas Wilson shows—and with acute perception—that there is no way to modify these causes, if and when they are found, in terms of public policy. As he puts it:

> Policy analysis, as opposed to causal analysis, begins with a different perspective. It asks . . . what is the condition one wants to bring into being, . . . what policy tools does a government . . . possess that might . . . produce at reasonable cost a desired alteration in the present condition.

He takes criminologists to task for being "long on theory and short on facts," agreeing at the same time that "explaining human behavior is a worthwhile endeavor." What Wilson objects to is the impossibility of applying "interesting facts" about crime to public policies regarding what is to be *done* about crime.

Other areas the author studied include the use of "random preventive police patrols and community service neighborhood policing teams" to augment the preventive force of police on the streets; the development of human relation skills among police; the complex problem of drug addiction; and the use of probation officers in reducing crime. The author reasons for rather than suggests or pleads for treatment of criminals on the basis of facts rather than myths. For example, he states that employment would reduce crime among young people *if* employment were more profitable than crime. In his words, "If criminal opportunities are profitable, many young persons will not take those legitimate jobs that exist," i.e., the risks of crime should be made more costly.

Some general conclusions arise from the maze of studies in the sociological and penological literature that Wilson cites. These are difficult to summarize. The main thrust of the author's essays (the book is made up of a series of essays separately published over some three years) is to criticize today's "pieties and pretensions." Wilson feels that not much can be done to change the rate of recidivism or juveniles' experimentation with petty crime or to increase the police apprehension rate. What can be done, he asserts, is to improve the judicial system—"reduce the arbitrary and socially irrational exercise of prosecutorial discretion . . . stop pretending judges know . . . how to provide 'individualized justice.' " In short, "Learn what works . . . and abandon . . . preconceptions about what *ought* to work."

The tone of this book is philosophical and ratiocinative. The author's criticisms and his materials are well chosen, but one misses a certain practical contact with offenders, in and out of institutions, in the writing. For example, in the thorny area of drug addiction, his statements that the pusher is a "myth" and that addicted youngsters do not turn to crime to support their habit are not consistent with my experience. Addiction, at least on the west coast, is a fixed, unassailable, unconquerable aspect of some segments of youthful life.

In spite of this and other criticisms that could be leveled against it, this book does state the myriad problems—social, ethical, and psychological—of crime in these United States. Professor Wilson's book is nothing if not "thinking about crime." It is recommended for all those who struggle with that morass.

WALTER BROMBERG, M.D.
Sacramento, Calif.

Borderline Conditions and Pathological Narcissism, *by Otto F. Kernberg, M.D. New York, N.Y., Jason Aronson, 1975, 354 pp., $15.00.*

Otto Kernberg's significant contributions to the understanding and treatment of patients with borderline personality organization and narcissistic personality are brought together in this new volume. It consists of 10 chapters: 7 were previously published, 1 was presented at a symposium in March 1974, and 2 are new. The previously published chapters include Kernberg's basic papers on borderline personality organization and narcissistic character and discuss diagnosis, prognosis, treatment principles, and countertransference issues. The new chapters present a critical review of the recent literature on differential diagnosis and

treatment, discuss the experience of emptiness, and clarify developmental aspects of narcissism.

The differences of opinion between Kernberg and Kohut about the nature of normal and pathological narcissism and their divergent views about the treatment of narcissistic disorders have been an exciting part of the literature during the past five years. Kernberg's views about narcissism and the formation of the grandiose self and his many other disagreements with Kohut are clearly delinated in this book.

Kernberg's work is solidly grounded in a Freudian psychoanalytic framework, which includes the contributions of such writers as Edith Jacobson and Heinz Hartmann. He also assimilates critical aspects of the work of some important British workers: Melanie Klein, Fairbairn, M. Little, P. Heimann, M. Khan, Guntrip, Rosenfeld, and Winnicott. Kernberg's synthesis leads to an object relations approach that makes use of their understanding of early object relations but maintains in theory and practice a careful developmental view of defenses, ego structure, and the self.

Kernberg delineates the developmental issues that distinguish psychotic, borderline, and narcissistic patients. He then describes the treatment implications that follow from these formulations. He reminds us constantly that object relations include relationships with outside objects as well as their intrapsychic representations.

The usefulness of this volume is obvious to anyone who is interested in studying the development of Kernberg's important work during the past 10 years. Because his papers require careful rereading, their publication in one volume assists the reader enormously. The 3 new chapters complement and expand the themes presented in the 7 other chapters and help give the book a sense of integration.

The publisher may have wanted to minimize the fact that this book contains some of Kernberg's previously published work rather than being a totally new book. One does not learn unambiguously until page 345 that 7 chapters were published before. I feel that Kernberg's papers on borderline and narcissistic patients benefit from publication in one volume and can be presented as such by any publisher with pride. This book will be used as one of the basic texts by clinicians and theoreticians who struggle to master an intellectual and emotional understanding of these difficult patients.

GERALD ADLER, M.D.
Boston, Mass.

Progress in Behavior Modification, Vol. 1, 1975, *edited by Michel Hersen, Richard M. Eisler, and Peter M. Miller. New York, N.Y., Academic Press (Harcourt Brace Jovanovich), 1975, 330 pp., $19.50.*

The past two decades have seen a tremendous growth of interest in what has been termed "behavior modification," most evident in the ever-increasing number of publications in the field. In reviewing these publications, one is often struck by the widely varied approaches, simplistically presented methodologies, exaggerated claims, and widespread generalizations that characterize many. The need for review publications to distill the truly significant contributions from the superfluous and present the material in a way that is balanced and thought-provoking is obvious. The editors of this book have set themselves the task of not only providing a review but continuing to do so on an annual basis.

The book consists of eight review articles that deal with historical perspectives on the field, the behavioral study and treatment of depression, behavioral treatment of phobias and obsessive-compulsive disorders, behavior modification with delinquents, token economies, individual behavior therapy, use of drugs and behavior analysis, and ethical and legal issues in behavior modification. All of the authors deserve to be commended for their enthusiasm with regard to their topics and the completeness of their reviews. More important, the authors have confined their remarks to critical appraisal of past works without attempting to promote any particular approach over another. A constant theme appears to be a plea for some standardization of procedures whereby comparisons can be made with more ease.

Deserving of special note is the chapter on ethical and legal issues. The author presents a very literate and stimulating view of the pitfalls facing behavioral therapists that should be required reading for all practitioners. It is gratifying that this topic receives as much attention as some of the more specific techniques in light of the trend toward patients' rights and voluntary refusal of treatment.

This book is not intended for the neophyte but to serve as a source book for those involved with behavior modification. It succeeds extremely well in this effort, and all involved are to be congratulated. One can only hope that the level of excellence demonstrated here can be maintained on an annual basis, as the editors propose.

Belmont, Mass.

Psychotherapy and Psychoanalysis: Theory, Practice, Research, *by Robert S. Wallerstein. New York, N.Y., International Universities Press, 1975, 465 pp., $17.50.*

The major focus of the papers in this stimulating volume concern psychotherapy and psychoanalysis as therapeutic modes and as bodies of theory, with the goal of delineating the conceptual and technical relationship between the two. The stimulus for many of the wide-ranging examinations of the many clinical and theoretical problems involved derived from the author's experience with the Psychotherapy Research Project of the Menninger Foundation. Added to this source were the persistent strivings of the author toward a scientifically valid, formalized method of study of clinical phenomena, reflected in his concerns about scientific rigor in research, education, criticism, and theorizing.

Three or four of the discussions cover differential treatment planning and prognostication in psychotherapy, the assessment of change in psychotherapy (including an excellent critical review of the writings on the problem of values in mental health), and an exhaustive study of the current state of psychotherapy. The last-mentioned discussion ranges from a review of the theory of psychoanalytic psychotherapy as reflected in the contributions of such authors as Glover, Knight, Colby, Eissler, Alexander, Fromm-Reichmann, Tarachow, Dewald, Gill, and, of course, Freud to a survey of the nonanalytic models of psychotherapy of Rogers, Ford and Urban, London, Frank, Wolpe, and others.

Although Wallerstein subscribes to Benjamin's idea that a comprehensive and articulated theory of psychotherapy of all sorts should be developed, he recognizes the need to establish an adequate theory of therapy for the psychoanalytically oriented approaches and, indeed, for psychoanalysis itself. Accordingly, in several papers he discusses a variety of viewpoints on the goals of psychoanalysis, the role

of prediction in theory building in psychoanalysis, and the relationship of psychoanalysis to psychotherapy. His summary of the views of the major contributors to the debate on this last-named question is illuminating, and his statement of the issues in the debate is expressed in such incisive questions as the following:

> What are the dividing lines across the range of psychotherapies conceptualized within the framework of psychoanalytic theory? Is the major dividing line between the expressive-uncovering therapeutic modalities (of which psychoanalysis is one) and the suppressive-supportive therapeutic modalities? Which divisions are meaningful, in theory and in practice?

In the middle portion of the book Wallerstein advocates serious attention to the task of developing effective research methods for the scientific validation of psychoanalytic theories and procedures. He includes chapters on research on the psychoanalytic process, research training for psychotherapists, and psychoanalytic education. Noting the scientific limitations of the informal clinical case study approach, he issues a call for research into investigative methodologies that will meet the complex problems of hypothesis testing and verification. He reviews the obstacles that have traditionally been found in the path of such research and research training and effectively demonstrates the necessity and possibility of expansion of efforts in these fields.

The last portion of the book is highlighted by a paper coauthored by Neil J. Smelser titled "Psychoanalysis and Sociology." This chapter starts with an acknowledgment of the inability of psychoanalysis to apply its laboriously acquired knowledge of intrapsychic configurations to the understanding of manifest behavior, especially in the sphere of social interaction. Similarly, the problem of values (that is, relative costs and benefits, moral and other, which must be taken into account in attempting to understand and plan purposive action) cannot be encompassed by psychoanalysis alone. This chapter exemplifies the fruitfulness of the "process of *mutual* informing and interactive modification . . . referred to as the principle of 'complementary articulation' between disciplines" and supports the authors' claim that psychoanalysis is in need of further technical and theoretical advances.

Spanning almost 25 years of scholarly attention to crucial clinical, theoretical, and interdisciplinary problems, Wallerstein's papers profit from being assembled in this admirable collection in several ways. Perhaps the most impressive is the resulting effectiveness in conveying the brilliant, searching, multifaceted style of inquiry that marks the author's consistant thoughtfulness in the course of his many different studies. Another illuminating gain from the combined presentation of this book is the opportunity to see how clinical and theoretical insights jointly contribute to the clarification of the nature and basis of psychotherapy vis-à-vis psychoanalysis. Still another gain is the provision of a sophisticated view of the influence on psychoanalysis of changes and developments in society, as they affect both our understanding of the human mind and our view of and responsibilities toward society.

The combined impact of these and many other incisively conveyed perspectives is to present to the student of psychoanalytic psychology the challenge of participating in the complex process of continuing discovery and change. Wallerstein's call for systematic surveys and explorations demonstrates his belief in the necessity to extend our knowledge, "the better to understand the varieties of functionings and malfunctionings of the human mind and the differentiated techniques by which to influence it toward restored harmony." This book states the relevant issues with great clarity and gives eloquent testimony to Wallerstein's contribution to the extension of our understanding.

HERBERT F. WALDHORN, M.D.
Great Neck, N.Y.

Mental Retardation and Developmental Disabilities: An Annual Review, VII, *edited by Joseph Wortis, M.D. New York, N.Y., Brunner/Mazel, 1975, 356 pp., $15.00.*

This book, the seventh in a series of annual reviews, is of value for the professional trying to keep up with the more significant developments in the rapidly widening field of mental retardation and developmental disabilities.

The 14 chapters are all of high quality, but they vary in style and purpose. Each chapter is valuable in its own right, however. They cover widely diverse areas and will be of greatest value to the professional who has had experience in the field or who is interested in a specific area.

The book can be divided roughly in half. Six chapters are directed primarily toward the clinician or physician and represent comprehensive and informative summaries of a highly technical nature, including clinical aspects, developmental neurophysiology, metabolism, epilepsy, and congenital malformations. Eight chapters deal with program areas, including early stimulation, computers in education, vocational training, normalization, self-help, personnel training, and a description of services in Sweden. The medical and nonmedical chapters present a sharp contrast in objectivity, scope, and purpose. The medical chapters are composed of objective and current literature reviews, and the behavioral chapters tend to be scholarly (the one on Sweden), editorializing (on vocational training), descriptive (on early stimulation), explanatory (on computers), or evangelistic (on normalization). A short summary of the chapters follows:

Kirman's summary of clinical aspects is written for the general practitioner, the obstetrician, or the pediatrician and covers the medical role and decision making in prenatal diagnosis and postnatal screening.

The chapter on developmental neurophysiology integrates a review of the literature on animal studies by Rose with a review of human studies by Tanguay.

Snyderman reviews metabolic disorders; his summary is organized according to disorders associated with specific amino acids and carbohydrates. He also includes prenatal diagnosis and newborn screening in his discussion.

The chapter on epilepsy by Corbett, Harris, and Robinson explores the complex interrelationships of this condition with etiology, other handicaps, and psychosocial determinants of mental retardation.

The two chapters dealing with congenital malformations by Jones and by Warkany and Dignan are erudite; they will be of value primarily for the pediatrician and the obstetrician.

The chapter by Caldwell, Bradley, and Elardo on early stimulation deals with a survey of current programs rather than with the basic research or the theoretical issues involved.

Wiegerink and Simeonsson's review of public schools deals competently with issues currently affecting the mentally retarded, such as segregation versus mainstreaming, litigation and due process, and teacher training.

Stolurow's treatment of computers in education provides a basic description of computers and their use but devotes far too little space to the use or projected use of computer assisted instruction with the mentally retarded.

Gold's chapter, which deals with vocational training, presents an extreme position regarding the capabilities of the mentally retarded for work and the injustices perpetrated by underestimations of their capability.

Zipperlin's discussion of normalization is a humanitarian and sometimes emotional statement of a bias.

Katz's discussion of self-help refers to mutual assistance in groups sharing a common need.

The chapter on personnel training by Zarfas, Lovering, and Robbins surveys in-service training models for personnel working with the mentally retarded.

Grunewals' description of services and developments in Sweden holds high interest value.

Therapeutics in Neurology, *by Donald B. Calne, B.Sc., D.M. Oxford, England, Blackwell Scientific Publications (Philadelphia, Pa., J.B. Lippincott Co., distributor), 1975, 317 pp., $32.00.*

This book is intended for physicians involved with the management of neurologic disorders. It might best be described as an up-to-date primer on the drugs available for neurologic disease. Surgical and physical therapies are only briefly mentioned.

The mechanism of drug action is considered in some detail, although the emphasis is placed on the practical aspects of patient treatment. Toxicity of drugs is discussed, and the optimal medical therapeutic approach is outlined.

This book should be in the consulting room of the physician who treats patients with neurologic disease.

DONALD W. MULDER, M.D.
Rochester, Minn.

Outgrowing Self-Deception, *by Gardner Murphy, with Morton Leeds. New York, N.Y., Basic Books, 1975, 167 pp., $8.95.*

This book is essentially a series of lessons teaching the development of perception as a skill. As mature adults we have extensive experience in perceptual learning, but that learning is clearly modifiable. Dr. Murphy argues, sometimes quite convincingly, that man is forever at work keeping vast areas of unwelcomed reality out of his view. Thus our perceptual learning has indeed been selective—most often to our disadvantage in terms of mature personality development.

Dr. Murphy's broad base of experience in a psychological climate allows him to draw extensively from mentors such as Bleuler and Murray. Few social scientists have had the broad base of Dr. Murphy's training and experience. The core emphasis of the book seems to be on the development of a feedback theory based on sound psychological principles from the life sciences.

The book is written with a broad readership in mind; it contains relatively little technical terminology and is certainly devoid of psychodynamic jargon. Dr. Murphy's professional maturity is clearly evident in his ability to summarize a considerable body of experimental evidence in a lucid, laymanlike manner. In fact, it borders on a do-it-yourself book for outgrowing self-deception. This manner of approach is graphically demonstrated in one chapter that specifically lists no fewer than 23 devices that may benefit man in coping with self-deception.

The introductory portion of the book lays a rather traditional-experimental groundwork for the subsequent self-improvement guidelines. The latter half of the book describes in detail some of the Freudian, Jungian, and Rogerian approaches to self-awareness and even includes some references to sensitivity training and biofeedback.

Dr. Murphy's style and enthusiasm will no doubt rub off on most readers and give them renewed motivation to pursue the possibility that there still are new psychophysiological horizons. The author indicates there are many ways to overcome the inner "dark spots" and that the best one is the one that works for you. I would submit that this book might well be the one that works for you. Read it.

WENDELL M. SWENSON, PH.D.
Rochester, Minn.

The Adolescent in Group and Family Therapy, *edited by Max Sugar, M.D. New York, N.Y., Brunner/Mazel, 1975, 282 pp., $13.50.*

An adolescent patient with emotional problems can be very difficult to reach in psychotherapy. This book is a collection of papers that explore several aspects of treating adolescent patients in group and family therapy. The book is divided into two parts: the first on group treatment and the second on family therapy. With an obvious emphasis on the psychodynamic forces in therapy, the book in remarkable detail explores the indications and contraindications for both modalities, the structure and setting of the group, group and family therapy dynamics, and a whole range of applications and adaptations of both modalities in treatment of the adolescent patient.

Using a finely balanced mixture of theory and practical application, this work explores a variety of adolescent problems, including descriptions of relevant psychodynamics of the patients involved in treatment. Practical aspects of therapy, including actual techniques of treatment, are included in every chapter. Interestingly, several authors describe not only their therapeutic techniques but also some of their efforts that have gone awry and their evaluation of the errors involved. Although the book emphasizes technique and theory of group and family therapy, many useful insights into the personal psychodynamics of both adolescents and adults are provided.

Dr. Max Sugar has done a remarkable job of editing a book on the relatively broad subjects of group and family therapies. Many edited books are difficult to read because of changes in style and emphasis between chapters. Dr. Sugar has avoided this pitfall with such great skill that it is not apparent to the reader when he has finished with one author and begun the next. Further, in only 282 pages can be found a wealth of information, presented in a concise and very readable format. Often I would find myself rereading passages, not because I did not understand what had been said but because there was even more to be gained.

Although the title might lead one to consider this book to

be of restricted interest, in fact anyone with an interest in group treatment, family therapy, adolescent patients, and even psychodynamic approaches to adult patients may find topics and concepts of interest to them in this work. I can heartily recommend *The Adolescent in Group and Family Therapy* as a book well worth reading.

E. L. LOSCHEN, M.D.
Springfield, Ill.

Self-Attitudes and Deviant Behavior, *by Howard B. Kaplan, Ph.D. Pacific Palisades, Calif., Goodyear Publishing Co., 1975, 181 pp., $8.95.*

The central thesis of this book is that deviant behavior results in improved self-attitudes. This thesis is based on the assumption that self-esteem is a dominant motive and is the normal outcome of the developmental process. Deviant behavior is viewed as a function of a person's membership in his various groups. The theory further states that there are three categories of deviant responses that function to alleviate subjective distress and thus satisfy the self-esteem motive. These functional categories are termed "avoidance of, attacks upon, and substitution for the normative environment."

The author tests his theory in chapters relating to "Dishonesty, Delinquency, and Criminality," "Drug Addiction and Drug Abuse," "Alcoholism and Alcohol Abuse," "Aggressive Behavior," "Suicidal Behavior," and "Mental Illness." In each chapter the relevant literature is examined to find out if the theory is supported. This task seems to be performed objectively, and a relationship is demonstrated in most classifications of deviant behavior.

As each form of deviant behavior is discussed the theory is reviewed, and examples from the literature are discussed and carefully examined. Copious notes are attached to each chapter; the author's style results in the reader's gaining easy understanding of the theoretical approach.

Of special interest to readers of this journal is the chapter on mental illness. Dr. Kaplan distinguishes between "predominantly expressive" and "predominantly instrumental" classes of mental illness in an attempt to relate these to traditional psychiatric diagnostic categories. He states,

> [The predominantly expressive category] here might include such traditionally defined neurotic disorders as anxiety neurosis, neurasthenic neurosis, and depressive neurosis; generally the psychophysiological disorders, and the transient situational disturbances; certain of the behavior disorders of childhood and adolescence such as overanxious reaction; and certain of the psychoses not attributed to physical conditions. . . . The predominantly instrumental category as it is defined here would include other of the traditionally defined neurotic disorders such as hysterical neurosis, phobic neurosis, and obsessive compulsive neurosis; generally the personality disorders; and several of the psychoses not attributed to physical conditions, particularly those disorders of thought and behavior characterized by reality distortion or other apparently self-protective behavior.

The theory does not attempt to explain the predominantly expressive disorders because they are not considered voluntary, motivationally relevant deviant patterns. This obviously leaves out a great many of the clinical issues psychiatrists work with and might be seen as a limitation in Kaplan's approach.

Another area in which more work could be done is in the exploration of the development of the predominance of the self-esteem motive. It would be interesting, for example, to compare this model of infantile development with the psychoanalytic model.

This carefully written book presents a workable approach to deviant behavior and is of interest to psychiatrists as well as to many other social scientists. As the theory is further developed, one hopes that material would emerge that would offer help to criminologists and present new ideas in rehabilitation and even primary prevention of mental disorders.

Portland, Me.

The Child as a Work of Art, *by Bennett Olshaker, M.D. New York, N.Y., Reader's Digest Press (E.P. Dutton & Co., distributor), 1975, 198 pp., $7.95.*

This is a book about the difficult art of parenthood. Perhaps even more compelling, it is a book that shows respect for children as unique human creatures who deserve far more than what today's society is willing to commit to its children. The standards that Dr. Olshaker applies to child rearing are very familiar, but they have been discarded by too many modern parents.

The topics discussed in various chapters include self-esteem and mutual respect, the development of independence, discipline, handling anger, and success and failure. A particularly well done chapter deals with the question of who should care for our children. In this chapter the author confronts the difficult subject of day care for children. He concludes,

> Hopefully, parents will remain the principal care takers of their own children whenever possible. This brings me again to what I feel is a very important point—more people should decide not to have children rather than to neglect them once they are born.

In summary, I found this to be a charming book, full of wisdom and truths that many modern parents have lost sight of. I would recommend it wholeheartedly for professionals as well as for young people considering the serious responsibilities of parenthood.

Research in Psychophysiology, *edited by Peter H. Venables and Margaret J. Christie. New York, N.Y., John Wiley & Sons, 1975, 437 pp., $32.00.*

OFFICIAL ACTIONS

1976 Annual Meeting: Registration and Related Information

The 129th annual meeting of the American Psychiatric Association will be held in Miami, Fla., May 10–14, 1976. The information here is what was available as of mid-January 1976. The official program book containing the scientific, business, and social program will be distributed in Miami at the time of registration. (The preliminary scientific program was printed in the February 20 issue of Psychiatric News.)

REGISTRATION

All registration will take place in the North Hall, Miami Beach Convention Center. The registration desk will be open:

Sunday, May 9—1:00 p.m. to 5:00 p.m.

Monday through Thursday, May 10–13—8:00 a.m. to 5:00 p.m.

Friday, May 14—8:00 a.m. to 10 a.m.

A registration fee of $15 per day, or $60 for all five days, is required from all nonmembers with the exception of 1) invited nonmember program participants who are presenting papers or who are session officers, and their immediate families, 2) discussants, 3) participants in morning and evening panels and their immediate families, and 4) the immediate families of APA members. Associate members, members-in-training, and their immediate families are also exempt from registration fees. The fee covers admission to the sessions and includes a badge and a copy of the official program. Badges are required for all sessions (including the opening session) and for the exhibit area. However, a badge does not cover admission to the business session of the Association, which is open only to members.

A $20 registration fee is required of visitors living outside the United States or Canada and of military personnel on active duty.

A $10 registration fee is required of the spouses and dependents of all nonmember registrants (excluding invited nonmember program participants).

A $15 registration fee is required of medical students, interns, residents, chaplains, nursing students, and students in the mental health professions and their spouses. Students must present a letter from their school or training facility instructor certifying their status.

The *Scientific Proceedings in Summary Form* for the 1976 annual meeting will be available throughout the week in the registration area of the Convention Center.

KEY LOCATIONS

All APA staff offices will be located in the Convention Center:

Staff Office	Room 154
Convention Office	North Lobby
Journal Office	Room 157
Press Offices	Rooms 150, 151
Local Arrangements	Room 153
Registration and Membership Information Center	North Hall
Information and Message Center	North Lobby
Spouse Hospitality Center	North Lobby
First Aid	North Lobby

INFORMATION AND MESSAGE CENTER

This center will be located in the North Lobby and will be manned during registration hours. Self-service message racks will be available for pick-up, deposit, and exchange of messages at all times, even when the message center is closed. Extremely urgent messages will receive the personal attention of APA staff members. All registrants are requested to check the message center periodically.

JOURNAL OFFICE

The office of the *American Journal of Psychiatry* will be in Room 157. The office will be open from 9:00 a.m. to 5:00 p.m., Monday through Thursday, and on Friday until 12:00 noon. Staff will be available to discuss any questions that authors who are presenting papers at the meeting may have. They particularly welcome the opportunity to confer with authors about tables and figures to be included in the papers.

Authors of numbered papers are reminded that all such papers are the property of the *Journal*. Permission must be secured from the Editor, Francis J. Braceland, M.D., before a paper may be offered for publication elsewhere. New research papers and papers presented at morning and evening panels do not automatically become the property of the *Journal*; however, authors may submit them for publication if they wish.

It is the policy of the *Journal* to publish only original material that has not been published elsewhere in any form and that is not being considered for publication elsewhere. "Publication" includes recording on videotape or audiotape and appearance in printed form.

WRITERS' WORKSHOP CANCELLED

The workshop on writing for scientific journals, which was scheduled to be held on May 9, has been cancelled.

CONVOCATION

The convocation will take place Wednesday, May 11, at 7:30 p.m. in the Fontainebleau Hotel, and will be followed by a special lecture.

FORUM ROOM

Rooms in the Convention Center are available for discussion of special issues during the course of the meeting. All groups who wish to schedule programs must apply for the use of these rooms by contacting the Convention Manager in the Convention Office, North Lobby. Groups who have secured use of a room and who wish to have a placard prepared for display in the registration area should contact the Convention Manager. Forums scheduled at the time of printing are listed in the official program under APA Activities.

SPOUSE HOSPITALITY CENTER

The Local Arrangements Committee will host a Spouse Hospitality Lounge in the Lobby of the Convention Center. Information on all leisure-time activities will be available Sunday through Thursday in this area. This area will also serve as the assembly point for all tours and special events.

DAY-CARE CENTER

APA has arranged with Ms. Maude Martin, Director of the Children's Corner Nursery School, 7118 Byron Ave., Miami Beach, Fla. 33141, to provide day care for infants and children 12 years and younger. The day-care center will operate from 7:30 a.m. to 5:30 p.m., Monday through Friday, and will charge $4.50 for four hours or less and $8.50 for up to nine hours. Advance reservations are recommended; coupons for this purpose can be found in various issues of *Psychiatric News*.

PROFESSIONAL TOURS

Information on tours to facilities of psychiatric interest in the Miami area may be obtained from members of the Local Arrangements Committee in the Spouse Hospitality Center.

PLACEMENT SERVICE

There will be a register available in the Membership Information Center for prospective employers and for those seeking positions.

MORNING AND EVENING PANELS

Morning panels will be held on Tuesday, Wednesday, and Thursday from 7:00 a.m. to 8:45 a.m. Breakfast may be obtained in regular hotel facilities. Evening panels will be held on Monday and Thursday at 8:00 p.m. All panels will be held at either the Fontainebleau, Eden Roc, Deauville, or Carillon hotels.

VIDEOTAPE SPECIAL SESSIONS

Videotape special sessions will be shown on wide-screen closed-circuit color TV in Room 101, Convention Center, from 9:00 a.m. to 12:00 noon and 2:00 p.m. to 5:00 p.m., Monday through Thursday, and from 9:00 a.m. to 12:00 noon on Friday.

FILMS

Films will be shown in Room 102, Convention Center, from 9:00 a.m. to 12:00 noon and 2:00 p.m. to 5:00 p.m., Monday through Thursday, and from 9:00 a.m. to 12:00 noon on Friday. Additional special features will also be shown.

SPECIAL LECTURES

APA will sponsor nine special lectures this year. Among these will be the Solomon Carter Fuller Lecture (Tuesday, from 10:00 a.m. to 12 noon), the Adolf Meyer Lecture (Tuesday, 1:00 p.m.), the Simon Bolivar Lecture (Wednesday, from 10:00 a.m. to 12:00 noon), and the Benjamin Rush Lecture (Wednesday, from 2:00 p.m. to 3:30 p.m.). In addition, Dr. Francis J. Braceland has been invited to give the Bicentennial Lecture on the theme of the convention, The Continuing Revolution: Benjamin Rush and His Successors (Tuesday, 10:00 a.m.).

SESSIONS ON NEW RESEARCH

These sessions will be held in the Miami Convention Center on Monday, from 2:00 p.m. to 5:00 p.m., Thursday, from 2:00 p.m. to 8:00 p.m., and Friday, from 9:00 a.m. to 12:00 noon. Program leaflets containing all details will be available at the registration desk.

CONTINUING EDUCATION CREDIT

In addition to other formal presentations, AMA Category I accredited courses will be offered for the first time. One hour of credit may be claimed for each hour of participation. Persons who want to participate in a course should consider possible conflicts with other annual meeting activities, including scientific papers. Check the February 20 issue of *Psychiatric News* for a complete program schedule of the annual meeting.

Those interested in participating in the courses MUST preregister, enclosing a $15 fee for each course. Registration closes April 15, 1976. Preregistration coupons and complete course descriptions can be found in various January-February issues of *Psychiatric News*.

ARTS AND CULTURE

A special production of the Broadway play "Equus" will take the place of the Annual Banquet. Performances will be at the Coconut Grove Theater on Sunday, May 9, at 8:00 p.m., and Tuesday, May 11, at 2:00 and 8:00 p.m. Complimentary general admission tickets will be available for APA members (two per member) in the registration area on a first-come, first-served basis. Shuttle bus service will be provided to and from each performance; details will be printed on the back of each ticket. "Question the Expert," a panel discussion with the author of "Equus," will be held on Wednesday, May 12, from 10:00 a.m. to 12 noon, in Room 201 of the Convention Center.

SHUTTLE BUS SERVICE

Bus service will be available between the Convention Center and nearby hotels. Route maps, hours of operation, and fare information will be available at the Information and Message Center.

EXHIBITS

Technical and scientific exhibits will be on display in North Hall, Convention Center, Monday through Thursday, 8:00 a.m. to 5:00 p.m.

SPECIAL BRUNCH

A champagne brunch with a special guest speaker will be held in honor of the spouses of APA officers on Tuesday, May 11, at 10:30 a.m. in the Fontaine Room of the Fontainebleau Hotel. Tickets for the brunch are $13.50 per person and may be purchased in the registration area. Buses will depart at 10:00 a.m. from the North Lobby.

Position Statement on Organizational Structure of State Mental Health Programs

This statement was approved by the Board of Trustees of the American Psychiatric Association at its December 5-6, 1975, meeting upon recommendation of the Council on Mental Health Services. It was prepared by the Council on Mental Health Services.[1]

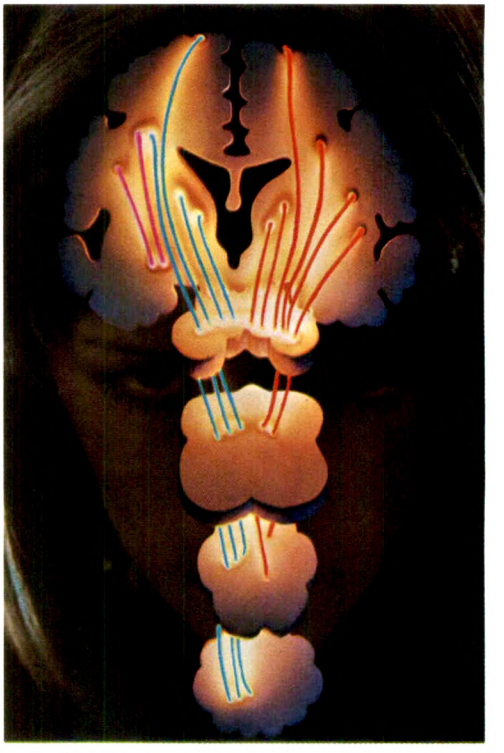
A STATE MENTAL health program can function most effectively when there is a separate and easily identified organizational component such as a department of mental health with full responsibility for the program.

The director of the mental health program should be a qualified psychiatrist with an appropriate administrative background, and he should have a qualified business administrator as one of his principal assistants. The director requires authority commensurate with the responsibility and accountability of the position.

Direct access to the Governor and to the legislature is necessary for the director to adequately perform the duties of his position.

The organizational placement of state services for the mentally retarded as a separate program or as a program combined with mental health services is most appropriately determined by considerations of the size and complexity of the program for the mentally retarded.

[1]The Council on Mental Health Services included: James C. Johnson, M.D., chairperson, Mildred Mitchell-Bateman, vice-chairperson, Israel Zwerling, M.D., Bruce W. Alspach, M.D., J.M. Stubblebine, M.D., Aubrey Dent, M.D., observer-consultant, and William B. Spriegel, M.D., Assembly of District Branches liaison.



Treating the chemocircuitry of depression

Depression as an organic disease

At one time, depression was thought to be predominantly a behavioristic, nonmetabolic abnormality. But recent work on CNS catecholamine metabolism strongly suggests that biochemical factors are involved.

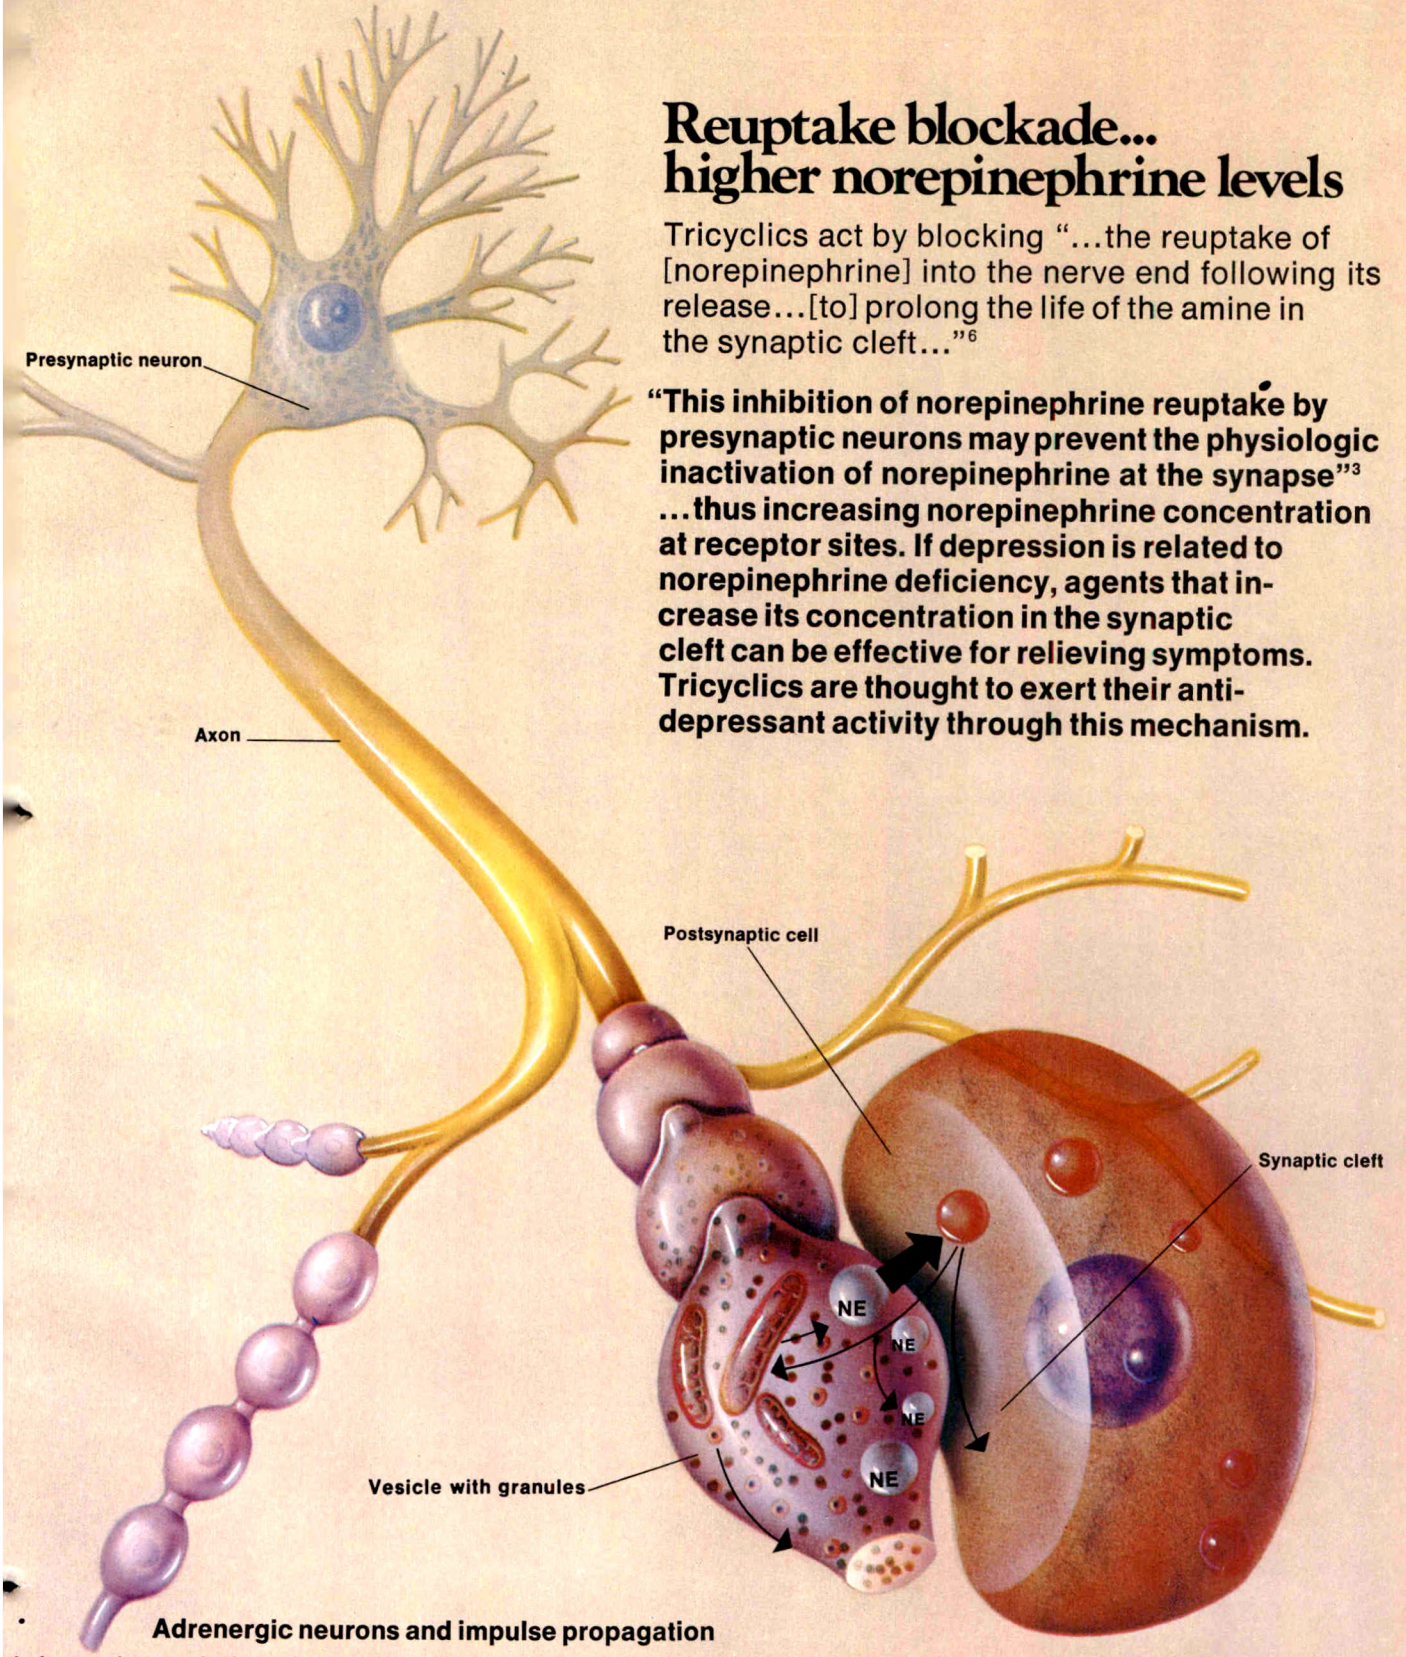
Theory of biogenic etiology

□ In individual nerve systems originating in the brainstem, impulses are relayed within each network by chemically distinct compounds—the biogenic amines.[1]

□ These compounds "... serve as neurotransmitters in brain sites that probably modulate feeling states, and other mental functions, that are disturbed in psychiatric disease."[2]

□ Amine systems involved in affective disorders[3] are:
norepinephrine (catecholamine)
dopamine (catecholamine)
serotonin (indoleamine)

There is a school of thought that associates catecholamines and affective disorders. According to this hypothesis, "... some, if not all, depressions are associated with an absolute or relative deficiency of catecholamines, particularly norepinephrine, at functionally important adrenergic receptor sites in the brain."[4]



"The possibility that depressed patients may have a functional deficiency of brain norepinephrine has gained considerable currency over the past decade."[5]

.and the efficacy of tricyclics

Reuptake blockade... higher norepinephrine levels

Tricyclics act by blocking "...the reuptake of [norepinephrine] into the nerve end following its release...[to] prolong the life of the amine in the synaptic cleft..."[6]

"This inhibition of norepinephrine reuptake by presynaptic neurons may prevent the physiologic inactivation of norepinephrine at the synapse"[3] ...thus increasing norepinephrine concentration at receptor sites. If depression is related to norepinephrine deficiency, agents that increase its concentration in the synaptic cleft can be effective for relieving symptoms. Tricyclics are thought to exert their antidepressant activity through this mechanism.

Adrenergic neurons and impulse propagation

Information coded as electric impulses arrives synapse via axons of presynaptic neurons.

Impulses cause "release" of norepinephrine ored in vesicles adjacent to the presynaptic embrane.

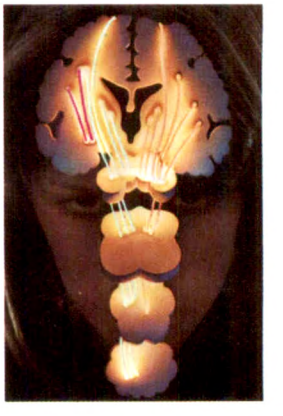
Neurotransmitter migrates across the synaptic

it either triggers a new impulse or inhibits activity in the postsynaptic cell.

□ Because of the complex nature of brain activity, this action must be terminated rapidly and the cleft primarily cleared through reuptake of the transmitter into the presynaptic cell.

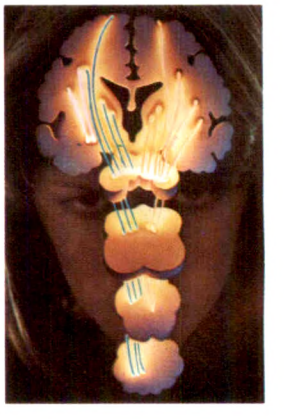
Tricyclics...the right choice in depression

Circuit functions and pharmacologic effects



Functioning of the biogenic amine systems, and how they are affected by therapeutic agents, underscore the value of tricyclics in depression.

The serotonin system: sedation/sleep



☐ Thought to regulate aspects of the sleep-wakefulness cycle and may be involved in REM sleep or dreaming.[2]
☐ Deficiency in turnover can produce symptomatology also present in depression.
☐ Some tricyclics, however, principally block the reuptake inactivation of serotonin.[6]
☐ **Activation of this system may therefore produce unwanted sedation.**

The dopamine system: motor activity

☐ Associated with normal posture and regulation of motor activity.
☐ Disturbed dopamine levels linked to symptoms of Parkinson's disease.
☐ "A possible relationship between decreased baseline... levels [of a dopamine metabolite] and decreases in motor activity in depressed patients has been suggested by some investigators..."[7]
☐ **Agents that influence this system can thus affect motor activity[6] and produce unwanted side effects.**

The norepinephrine system: mood

☐ Plays a major role in affective states.
☐ Deficiencies of norepinephrine linked to depression.
☐ Norepinephrine levels may be raised by psychomotor stimulants which cause release and block reuptake... by MAO inhibitors which block intraneuronal metabolism ...and by tricyclics through reuptake blockade.[1]
☐ Of these agents, the "most useful are the tricyclics."[6] They are preferred for their greater safety[8] and lower incidence of side effects.[9]
☐ **But tricyclics vary in their degree of interaction with other circuits—not only the catecholamines, but serotonin and acetylcholine as well.[10]**

Pertofrane®...the right choice in tricyclics
(desipramine hydrochloride NF)

Consider the chemistry

'...qualitative and quantitative changes in the biochemical, pharmacological and clinical spectrum...[were produced by] the elimination of one of the *N*-methyl groups in the terminal amino group of imipramine to yield desipramine."[11]

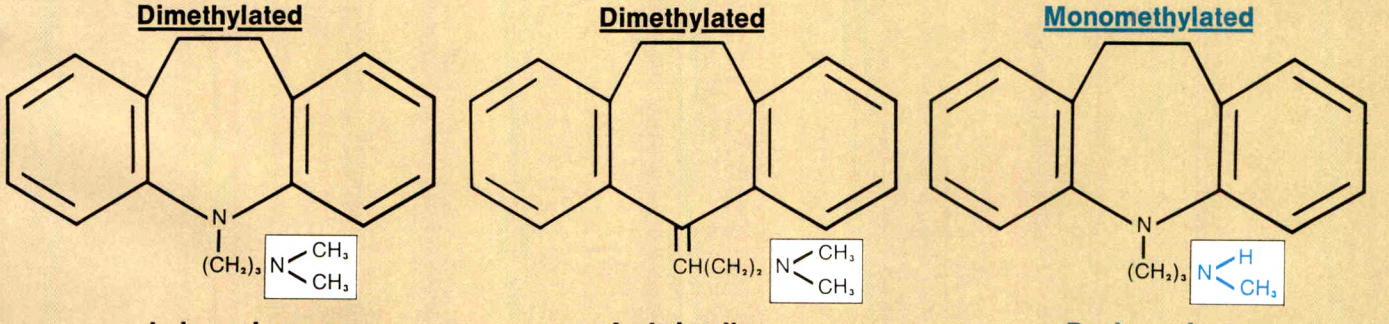
"...monomethylated forms of tricyclic antidepressants...are generally much more potent inhibitors of catecholamine re-uptake than dimethylated forms ...[whereas] dimethylated tricyclic antidepressants are more potent anticholinergics than the monomethylated forms."[12]

Dimethylated drugs are more potent serotonin blockers than monomethylated analogs. "Imipramine slows the turnover rate of [serotonin], an effect not shared by desipramine..."[13]

'...compared to imipramine, [desipramine] is more 'procatechol' than 'proindole.'"[6]

...and the clinical implications

Rapid onset of action



Pertofrane has been found in some studies[14,16,19] to have a more rapid onset of action than imipramine. This relatively rapid onset of action may bring about prompt therapeutic response.

In a recent double-blind study comparing desipramine and amitriptyline, "the activity of desipramine becomes manifest rapidly and its beneficial effects further improve over time."[15]

Less sedative effect

Desipramine HCl shows good to excellent antidepressant effect yet is only mid-range in sedation.[6]

In a recent double-blind study comparing desipramine and amitriptyline in outpatients with depressive neurosis, while desipramine was equal or superior to amitriptyline in improving anxiety/depression and sleep disturbance factors, amitriptyline produced sedation in significantly more patients than did desipramine.[15]

Imipramine **Amitriptyline** **Desipramine**

Selection of the right tricyclic for a particular patient can be based on structural activity relationships. And the profile of activity for a particular agent frequently depends on whether it is dimethylated or monomethylated.

Please see back cover for full prescribing information.

When activity is important

the neurochemistry's right for Pertofrane® (desipramine hydrochloride NF)

Proven clinical efficacy

☐ "...seems ideally suited to use in an active ambulatory patient population...[because of] its significant improvement of the depressed mood, work and activities..."[15]

☐ Effectiveness well documented in over a decade of clinical use.[9,16–18]

Prompt onset of action

☐ Relief may begin in 2 to 5 days—but full therapeutic effect is seldom seen before 2 weeks.

☐ Rapid onset of action[11,14,15,16,19] is particularly useful in patients who must continue to function actively during the course of therapy.

Mid-range sedation[6]

☐ Relieves associated mild anxiety/agitation, yet is only mid-range in sedative effect.

☐ "There is no problem of drowsiness"[16]—especially important when normal levels of daily activity must be maintained during treatment.

Compatible with tranquilizers/sedatives

☐ Where necessary, may be used with antianxiety or hypnotic agents.[16]

☐ Permits individualization of therapy when mild anxiety or agitation accompanies depression.

Provides dosage flexibility

☐ The therapeutic range is from 25 to 200 mg. daily. Patients may start at 25 mg. t.i.d. and dosage may be increased up to 200 mg./day according to patient needs.

Please see back cover for full prescribing information.

Pertofrane® (desipramine hydrochloride NF)

when activity is important

INDICATIONS: PERTOFRANE is indicated for the relief of mental depression (see Note before How Supplied section for additional information on depressive symptomatologies often responsive to this drug).

CONTRAINDICATIONS: The use of PERTOFRANE concomitantly or within two weeks of the administration of MAO inhibitors, is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse reactions can be serious, or even fatal. When it is desired to substitute PERTOFRANE in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation allows, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed.

The drug is contraindicated following recent myocardial infarction.

Patients with a known hypersensitivity to tricyclic antidepressants should not be given PERTOFRANE.

WARNINGS: As with other potent antidepressants, an activation of the psychosis may occasionally be observed in schizophrenic patients.

Due to the drug's atropine-like effects and sympathomimetic potentiation, PERTOFRANE should be used only with the greatest care in patients with narrow-angle glaucoma and with urethral or ureteral spasm.

Likewise, only when patient need outweighs the risk of serious adverse reactions should the drug be used in the presence of any of the following conditions: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (this agent has been shown to lower the seizure threshold).

In some instances, desipramine and the parent compound, imipramine, have been shown to block the pharmacologic action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents.

Hypertensive episodes have been observed during surgery in patients on desipramine hydrochloride therapy.

The concurrent use of other central nervous system drugs or alcohol may potentiate the adverse effects of desipramine hydrochloride. Since many such drugs may be used during surgery, it is recommended that desipramine hydrochloride be discontinued for as long as the clinical situation will allow prior to elective surgery.

Patients should be cautioned about the possibility of impaired ability to operate a motor vehicle or other dangerous machinery.

Usage in Pregnancy: Although teratogenic studies in mice, rats and rabbits have revealed no adverse effects, safe use of this drug in women who are or may become pregnant has not been definitely established. Therefore, PERTOFRANE should be withheld from these women unless the clinical situation warrants the potential risk.

In view of the lack of experience in children, the drug is not recommended for use in patients under twelve years of age.

Elderly and adolescent patients can usually be managed on lower dosage than that recommended for other patients and may not tolerate higher doses as well because of an increased incidence of adverse reactions.

PRECAUTIONS: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until remission occurs. These patients require careful supervision and protective measures during therapy.

Anxiety and increased agitation have been reported, particularly where depression is not the primary disorder. A shift to hypomanic or manic excitement may occur during therapy. Such reactions may necessitate discontinuation of the drug.

Although the anticholinergic activity of the drug is weak, in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents), atropine-like effects may be more pronounced (e.g. paralytic ileus).

Caution should be observed in prescribing the drug in hyperthyroid patients and in those receiving thyroid medications. Transient cardiac arrhythmias have occurred in rare instances.

In all patients undergoing extended courses of therapy, periodic blood and liver studies for signs of toxicity should supplement careful clinical observations.

ADVERSE REACTIONS: PERTOFRANE (desipramine hydrochloride) is well tolerated by most patients and severe complications or adverse reactions are infrequent. Those most often reported cause little discomfort and seldom require discontinuation of the drug.

Nervous System: Dizziness, drowsiness, insomnia, headache and disturbed visual accommodation have been reported with the drug. In addition, tremor, unsteadiness, tinnitus and paresthesias have been reported. Occasionally, mild extrapyramidal activity, falling and neuromuscular incoordination have been seen. A confusional state (with such symptoms as hallucinations and disorientation) may be produced, particularly in older patients and at higher dosage, and may require discontinuation of the drug. Changes in EEG patterns have been observed. Epileptiform seizures may occur. A reduction in dosage may help control some of these adverse reactions.

Gastrointestinal Tract: Anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea have been reported in patients receiving PERTOFRANE.

Skin: Skin rashes (including photosensitization), perspiration and flushing sensations have been reported during therapy.

Liver: Transient jaundice, apparently of an obstructive nature, and liver damage have been observed in rare cases. Elevation in transaminase and changes in alkaline phosphatase have occurred and should indicate repeated liver-function profiles. If progressive elevation occurs, the drug should be discontinued.

Blood Elements: Bone-marrow depression, agranulocytosis, thrombocytopenia and purpura have been reported. If these occur, the drug should be discontinued. Transient eosinophilia has been observed in some instances.

Cardiovascular System: Orthostatic hypotension and tachycardia have been observed but seldom require discontinuation of treatment. Patients who require concomitant vasodilating therapy should be carefully supervised, particularly during the initial phases.

Genitourinary System: Urinary frequency or retention and impotence have been reported.

Endocrine System: Occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement have been reported with PERTOFRANE (desipramine hydrochloride). In addition, decreased libido and estrogenic effect have been noted. The exact relationship of these adverse effects to the administration of the drug has not been established.

Sensitivity: Urticaria and rare instances of drug fever and cross-sensitivity with imipramine have been observed.

DOSAGE AND ADMINISTRATION: *All Patients Except Geriatric and Adolescent:* Optimal results are obtained at a dosage of approximately 150 mg./day. PERTOFRANE may be administered as two 25 mg. capsules or one 50 mg. capsule t.i.d. (150 mg. daily). When necessary, dosage may be increased, after initiation of therapy, up to 200 mg. daily in divided doses. Continued therapy at the optimal dosage level should be maintained during the active phase of the depression. It is recommended that a lower maintenance dosage be continued for at least two months after a satisfactory response has been achieved.

In cases of relapse due to premature withdrawal of the drug, a prompt response may be obtained by immediate resumption of treatment.

Geriatric and Adolescent Patients: Elderly and adolescent patients can usually be managed on lower dosage and may not tolerate higher doses as well as other patients. Therapy in these age groups may be initiated with 25 to 50 mg. daily. Dosage may be increased according to response and tolerance, but it is generally unnecessary to exceed 100 mg. daily in these patients. It is recommended that a lower maintenance dosage be continued for at least two months after a satisfactory response has been achieved.

Mild anxiety and agitation which often accompany cases of depression usually remit as the depression responds to PERTOFRANE. Occasionally, however, when anxiety and agitation are more serious, the adjunctive use of a sedative or tranquilizing agent may be indicated.

NOTE: Depressions which are most responsive to PERTOFRANE may be described in terms of "target symptoms." These include: despondency, sadness and depressed mood; fatigue; lack of interest and emotional response; helplessness, hopelessness, pessimism and despair; feelings of incapacity and inferiority; psychomotor retardation and inhibition; delusions of guilt and unworthiness; psychosomatic complaints; insomnia anorexia and weight loss; depression-related anxiety and agitation; suicidal drive.

It should be borne in mind that these "target symptoms" of depression assume their proper significance only after careful history, physical and mental evaluations and other investigative procedures have confirmed a diagnosis of one of the several types of depression.

HOW SUPPLIED: 25 mg. Capsules (pink), bottles of 100 and 1000 (NSN 6505-00-913-0382A). Also, 50 mg. Capsules (maroon and pink), bottles of 100 and 1000; single-dose blister packs, boxes of 500.

USV PHARMACEUTICALS

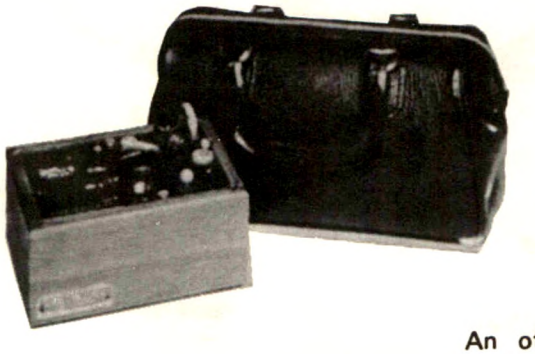
USV Pharmaceutical Mfg. Corp.
Manati, P.R. 00701

MORE THAN 30 YEARS...

have proven the dependability and effectiveness of REITER ELECTROSTIMULATORS in psychiatry! Research and constant improvements to meet the standards of improved techniques have kept Reiter instruments

THE WORLD'S MOST ACCEPTED ELECTROSTIMULATORS

The Two Popular Models— **PORTABLE FOR OFFICE AND CLINIC**



The Reiter MODEL SOS—THE ONE INSTRUMENT FOR ALL ESTABLISHED TECHNIQUES, provides the fullest range of safest therapies. For painless, gentle stimulation of the conscious patient to relieve anxiety, depression, etc. Maximum safety, no additives—patient conscious and cooperating with therapy.

The SOS has also been used universally for Convulsive Therapy, Non-Convulsive Therapies, Electro-Sleep Therapy, Focal Treatment, Mono-Polar Treatment, Barbiturate Coma (and other respiratory problems), Mild Sedac, Deep Sedac Therapy, Pre-Convulsive Sedac, Post-Convulsive Sedac, Neurological Conditions, and Measurement Procedures.

Available with this redesigned model, on request, the following special-purpose electrodes —a Multi-Polar "Collar" type for Sleep Therapy, a "Horseshoe" assembly for quicker, surer application with one hand at last moment before ECT treatment, and a "Unilateral" type assembly.

Also built-in on request, an **automatic switch** for quicker build up to therapeutic ranges of Sedac.

SPECIAL MODEL SOS available without unidirectional convulsive current.

The Reiter Compact MOL-AC II—The smallest, lightest, least expensive and most reliable, clinically proven A.C. shock therapy instrument. Less confusion than from similar A.C. equipment. Now available with redesigned, improved panel. This compact instrument is only 3 x 5 inches, weighs but 3 lbs., yet provides full positive control of glisando effect over entire voltage range, as well as a positive manual control of time. There are NO complicated settings of dials, NO waiting for resetting of time devices, no warm-up delays.

An officially approved, extremely durable instrument which has earned world-wide professional acceptance, the MOL-AC II is economically priced with a fine, genuine leather physician's bag included.

Other Models Still Available: The CW47, original therapeutic cerebral stimulator with only 3 of the 9 treatment current selections available on Model SOS.

See us at Booth F5 at the Annual Meeting

ANTABUSE: "Social security" for the alcoholic who wants to stop drinking...

The temptation is resisted, ANTABUSE (disulfiram) represents the security alcoholics need in any situation. They are better able to abstain from drinking because they know the consequences of taking "even one."

until psychiatric support can do the rest

Undoubtedly it will take considerable time for psychotherapy to help the chronic alcoholic. As a psychiatrist, you have undoubtedly selected the patients who are best motivated to stay with ANTABUSE while you attempt to deal with the underlying emotional problems. And, of course, you know the importance of reminding patients of the serious consequences of drinking while on ANTABUSE.

Once sober, and well into treatment, the alcoholic, at your discretion, can participate in a total treatment program which makes use of various supportive resources in the community. In the meantime, ANTABUSE can help the chronic alcoholic abstain from drinking.

BRIEF SUMMARY
(For full prescribing information, see package circular.)

ANTABUSE® (disulfiram) in Alcoholism

INDICATION: ANTABUSE is an aid in the management of selected chronic alcoholic patients who want to remain in a state of enforced sobriety so that supportive and psychotherapeutic treatment may be applied to best advantage. (Used alone, without proper motivation and without supportive therapy, ANTABUSE is not a cure for alcoholism, and it is unlikely that it will have more than a brief effect on the drinking pattern of the chronic alcoholic.)

CONTRAINDICATIONS: Patients who are receiving or have recently received metronidazole, paraldehyde, alcohol, or alcohol-containing preparations, e.g. cough syrups, tonics, and the like, should not be given ANTABUSE.

ANTABUSE is contraindicated in the presence of severe myocardial disease or coronary occlusion, psychoses, or hypersensitivity.

WARNINGS: ANTABUSE should never be administered to a patient when he is in a state of alcohol intoxication or without his full knowledge.

The physician should instruct relatives accordingly.

The patient must be fully informed of the ANTABUSE-alcohol reaction. He must be strongly cautioned against surreptitious drinking while taking the drug, and he must be fully aware of possible consequences. He should be warned to avoid alcohol in disguised form, *i.e.* in sauces, vinegars, cough mixtures, and even aftershave lotions and back rubs. He should also be warned that reactions may occur with alcohol up to 14 days after ingesting ANTABUSE.

THE ANTABUSE-ALCOHOL REACTION: ANTABUSE plus alcohol, even small amounts, produces flushing, throbbing in head and neck, throbbing headache, respiratory difficulty, nausea, copious vomiting, sweating, thirst, chest pain, palpitation, dyspnea, hyperventilation, tachycardia, hypotension, syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion. In severe reactions there may be respiratory depression, cardiovascular collapse, arrhythmias, myocardial infarction, acute congestive heart failure, unconsciousness, convulsions, and death.

The intensity of the reaction varies with each individual, but is generally proportional to the amounts of ANTABUSE (disulfiram) and alcohol ingested. Mild reactions may occur in the sensitive individual when the blood alcohol concentration is increased to as little as 5 to 10 mg. per 100 cc. Symptoms are fully developed at 50 mg. per 100 cc., and unconsciousness usually results when the blood alcohol level reaches 125 to 150 mg.

The duration of the reaction varies from 30 to 60 minutes to several hours in the more severe cases, or as long as there is alcohol in the blood.

DRUG INTERACTIONS: Disulfiram appears to decrease the rate at which certain drugs are metabolized and so may increase the blood levels and the possibility of clinical toxicity of drugs given concomitantly.

Disulfiram should be used with caution in those patients receiving diphenylhydantoin and its congeners, since toxic levels of these antiepileptic agents have been reported during concomitant disulfiram therapy.

It may be necessary to adjust the dosage of oral anticoagulants upon beginning or stopping disulfiram, since disulfiram may prolong prothrombin time.

Patients taking isoniazid when disulfiram is given should be observed for the appearance of unsteady gait or marked changes in mental status and the disulfiram discontinued if such signs appear.

CONCOMITANT CONDITIONS: Because of the possibility of an accidental ANTABUSE-alcohol reaction, ANTABUSE (disulfiram) should be used with extreme caution in patients with any of the following conditions: diabetes mellitus, hypothyroidism, epilepsy, cerebral damage, chronic and acute nephritis, hepatic cirrhosis or insufficiency.

USAGE IN PREGNANCY: The safe use of this drug in pregnancy has not been established. Therefore, ANTABUSE (disulfiram) should be used during pregnancy only when, in the judgment of the physician, the probable benefits outweigh the possible risks.

PRECAUTIONS: It is suggested that every patient under treatment carry an Identification Card, stating that he is receiving ANTABUSE and describing the symptoms most likely to occur as a result of the ANTABUSE-alcohol reaction. In addition, this card should indicate the physician or institution to be contacted in emergency. (Cards may be obtained from Ayerst Laboratories upon request.)

Alcoholism may accompany or be followed by dependence on narcotics or sedatives. Barbiturates have been administered concurrently with ANTABUSE (disulfiram) without untoward effects, but the possibility of initiating a new abuse should be considered.

Base line and follow-up transaminase tests (10-14 days) are suggested to detect any hepatic dysfunction that may result with ANTABUSE therapy. In addition, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

ADVERSE REACTIONS: (See Contraindications, Warnings, and Precautions.)

Occasional skin eruptions are, as a rule, readily controlled by concomitant administration of an antihistaminic drug.

In a small number of patients, a transient mild drowsiness, fatigability, impotence, headache, acneform eruptions, allergic dermatitis, or a metallic or garlic-like aftertaste may be experienced during the first two weeks of therapy. These complaints usually disappear spontaneously with the continuation of therapy or with reduced dosage.

Psychotic reactions have been noted, attributable in most cases to high dosage, combined toxicity (with metronidazole or isoniazid), or to the unmasking of underlying psychoses in patients stressed by the withdrawal of alcohol.

There have been reports of polyneuritis and peripheral neuritis, and rare instances of optic neuritis. One case of cholestatic hepatitis has been reported, but its relationship to ANTABUSE has not been unequivocally established.

DOSAGE AND ADMINISTRATION: ANTABUSE (disulfiram) should never be administered until the patient has abstained from alcohol for at least 12 hours.

INITIAL DOSAGE SCHEDULE: In the first phase of treatment, a maximum of 500 mg. daily is given in a single dose for one to two weeks. Although usually taken in the morning, ANTABUSE may be taken on retiring by patients who experience a sedative effect. Alternatively, to minimize, or eliminate, the sedative effect, dosage may be adjusted downward.

MAINTENANCE REGIMEN: The average maintenance dose is 250 mg. daily (range, 125 to 500 mg.); it should not exceed 500 mg. daily.

NOTE: Occasional patients, while seemingly on adequate maintenance doses of ANTABUSE (disulfiram), report that they are able to drink alcoholic beverages with impunity and without any symptomatology. All appearances to the contrary, such patients must be presumed to be disposing of their tablets in some manner without actually taking them. Until such patients have been observed reliably taking their daily ANTABUSE tablets (preferably crushed and well mixed with liquid), it cannot be concluded that ANTABUSE is ineffective.

DURATION OF THERAPY: The daily, uninterrupted administration of ANTABUSE must be continued until the patient is fully recovered socially and a basis for permanent self-control is established. Depending on the individual patient, maintenance therapy may be required for months or even years.

TRIAL WITH ALCOHOL: During early experience with ANTABUSE, it was thought advisable for each patient to have at least one supervised alcohol-drug reaction. More recently, the test reaction has been largely abandoned. Furthermore, such a test reaction should never be administered to a patient over 50 years of age. A clear, detailed, and convincing description of the reaction is felt to be sufficient in most cases.

However, where a test reaction is deemed necessary, the suggested procedure is as follows:

After the first one to two weeks' therapy with 500 mg. daily, a drink of 15 cc. (½ oz.) of 100 proof whiskey or equivalent is taken slowly. This test dose of alcoholic beverage may be repeated once only so that the total dose does not exceed 30 cc. (1 oz.) of whiskey. Once a reaction develops, no more alcohol should be consumed. Such tests should be carried out only when the patient is hospitalized, or comparable supervision and facilities, including oxygen, are available.

MANAGEMENT OF ANTABUSE (DISULFIRAM)-ALCOHOL REACTION: In severe reactions, whether caused by an excessive test dose or by the patient's unsupervised ingestion of alcohol, supportive measures to restore blood pressure and treat shock should be instituted. Other recommendations include: oxygen, carbogen (95 per cent oxygen and 5 per cent carbon dioxide), vitamin C intravenously in massive doses (1 Gm.), and ephedrine sulfate. Antihistamines have also been used intravenously. Potassium levels should be monitored particularly in patients on digitalis since hypokalemia has been reported.

HOW SUPPLIED: No. 809—Each tablet (scored) contains 250 mg. disulfiram, in bottles of 100. No. 810—Each tablet (scored) contains 500 mg. disulfiram, in bottles of 50 and 1,000.

ANTABUSE®
BRAND OF DISULFIRAM

The TRIAVIL® Potential in the management of moderate to severe anxiety with depression

When time and talk are not enough...
The therapist is the primary catalyst for change in the psychotherapeutic relationship. However, when patients suffer from moderate to severe anxiety with depression, there are situations when TRIAVIL can often be a useful adjunct.

...TRIAVIL may help
There are three important benefits you may expect when TRIAVIL is part of the treatment program: (1) When symptoms of moderate to severe anxiety or agitation with depression are relieved, the patient may become more accessible and cooperative. (2) As somatic manifestations are controlled, attention may be focused on underlying causative factors. (3) Symptomatic relief may enable the patient to function more effectively in his daily life while your work with the patient progresses.

Tablets TRIAVIL are available in four different combinations affording flexibility and individualized dosage adjustment. Since it is simpler to remember to take one tablet rather than several (particularly in multiple daily doses), your patients on TRIAVIL will be more likely to take proper doses of the medication.

TRIAVIL is contraindicated in CNS depression from drugs; in the presence of evidence of bone marrow depression; and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For a brief summary of prescribing information, please turn to the following page.

when patients exhibit moderate to marked anxiety or agitation with symptoms of depression

TRIAVIL® **containing perphenazine and amitriptyline HCl**

a tranquilizer-antidepressant

for highly effective relief of depression with moderate anxiety

TRIAVIL®

containing perphenazine and amitriptyline HCl a tranquilizer-antidepressant

Available:

TRIAVIL® 2-25: Each tablet contains 2 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 2-10: Each tablet contains 2 mg perphenazine and 10 mg amitriptyline HCl

TRIAVIL® 4-25: Each tablet contains 4 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 4-10: Each tablet contains 4 mg perphenazine and 10 mg amitriptyline HCl

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Do not give concomitantly with MAOI drugs because hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. Allow minimum of 14 days between therapies, then initiate therapy with TRIAVIL cautiously, with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given with guanethidine or similarly acting compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, particularly in high doses, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. Caution patients performing hazardous tasks, such as operating machinery or driving motor vehicles, that drug may impair mental and/or physical abilities. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Side effects may be any of those reported with phenothiazine drugs: extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and that the full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; hypnotic effects; pigmentary retinopathy; corneal and lenticular pigmentation; occasional lassitude, muscle weakness, mild insomnia. Other adverse reactions reported with various phenothiazine compounds include blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); liver damage (jaundice, biliary stasis); grand mal convulsions; cerebral edema; polyphagia; photophobia; skin pigmentation; and failure of ejaculation.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness; weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; jaundice; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

Where The Action Is—

For more than a decade the general hospital psychiatric unit has been the principal locus of inpatient treatment. This latest Joint Information Service national survey brings up to date its earlier—and the original—study of this important component of the psychiatric scene. It reveals that the remarkable rate of growth held up, showing an increase of 50 percent in the number of units between 1963 and 1971, and an increase of 46 percent in the number of admissions. And it verifies that general hospital psychiatry has become increasingly comprehensive, with an impressively high level of outpatient service, emergency service, and even consultation to community agencies. Indeed, the general hospital accounts for several times as much service and activity as the widely heralded federally supported community mental health center.

This study also involves the private psychiatric hospitals, which have not changed much in number but are admitting about 10,000 more patients than in 1964—and they, too, are providing a remarkably comprehensive program.

It's your responsibility to be well-informed about these extraordinarily significant and vital pieces of American psychiatric service. You can do so by sending the order form below.

Valium® (diazepam) Close-Up

Product information for psychiatrists

If your patient is taking one of these...

Primary medications

anticoagulants
antacids
cardiac glycosides
diuretics
vasodilators
anticholinergics

Psychotropics/CNS depressants

alcohol
phenothiazines
narcotics
barbiturates
hypnotics
MAO inhibitors
minor tranquilizers
antidepressants

Anticonvulsants

ROCHE

you should know this about Valium® (diazepam)

Valium is frequently used with most classes of these primary medications. Clinically significant drug interactions have not been reported to date.

Potentiation may occur with other CNS depressants. Careful consideration should be given to the pharmacology of these compounds when used concomitantly with Valium.

As with other agents which have anticonvulsant activity, the possibility of increase in frequency and/or severity of grand mal seizures may require an increase in dosage of standard anticonvulsants.

Valium® (diazepam) ℞

2-mg, 5-mg, 10-mg scored tablets

Before prescribing, please see following page for a summary of product information.

Valium® (diazepam)

2-mg, 5-mg, 10-mg scored tablets

can relieve psychoneurotic anxiety and its associated depressive symptoms

Prompt, effective action. Valium works rapidly to relieve pronounced psychic tension in patients overreacting to stress and in psychoneurotic patients.

Wide margin of safety. Valium is generally well tolerated and in usual dosages rarely produces significant adverse reactions.

Dosage flexibility. Scored Valium 2-, 5-, 10-mg tablets give you dosage flexibility no tranquilizer capsule can match.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

The vulnerable ages

The first epileptic seizure is most likely to occur during early childhood and at the onset of puberty

About 9 out of 10 epileptics experience their first seizure before the age of 20—with the highest incidence between 5 and 7, when children start school, and at the onset of puberty, a time of physiological and psychic turmoil.[1] The most common type, grand mal, occurs in approximately 75% of epileptic children,[1] and more than 50% of patients who suffer initially from petit mal develop grand mal seizures before they reach the age of 16.[2]

Mysoline (primidone) for control of grand mal, psychomotor and focal epilepsy

At the onset and afterwards— used alone or as concomitant therapy, MYSOLINE may reduce the frequency and severity of major motor seizures—or even eliminate them. *Excellent* for control of grand mal. Valuable for control of psychomotor[1,3,4] and focal epilepsy as well.[5]

Add Mysoline when control with other anticonvulsants is inadequate—As concomitant therapy, MYSOLINE can improve seizure control in grand mal and psychomotor epilepsy. The combined use of phenobarbital, diphenylhydantoin, and MYSOLINE may have additive anticonvulsant effects without additive side effects.[6]

Change to Mysoline when other anticonvulsants fail— A changeover to MYSOLINE is frequently warranted when other anticonvulsants must be discontinued because of important side effects, or when grand mal seizures are refractory to phenobarbital, with or without diphenylhydantoin.[7]

Mysoline® (primidone)

may be the start of a better life for the epileptic

initial and maintenance therapy for
grand mal, psychomotor and focal epilepsy

BRIEF SUMMARY
(For full prescribing information, see package circular.)

MYSOLINE® Brand of PRIMIDONE
Anticonvulsant

ACTIONS: MYSOLINE acts on the central nervous system to raise seizure threshold or alter seizure pattern. The mechanism(s) of action of anticonvulsant drugs is not known.

Primidone has anticonvulsant activity *per se*. In addition, its two metabolites possess anticonvulsant qualities. The major metabolite is phenylethylmalonamide (PEMA); the other is phenobarbital. In addition to its own anticonvulsant potential, PEMA potentiates phenobarbital.

INDICATIONS: MYSOLINE, either alone or used concomitantly with other anticonvulsants, is indicated in the control of grand mal, psychomotor, and focal epileptic seizures. It may control grand mal seizures refractory to other anticonvulsant therapy.

CONTRAINDICATIONS: Primidone is contraindicated in: 1) patients with porphyria and 2) patients who are hypersensitive to phenobarbital (see ACTIONS).

WARNINGS: The abrupt withdrawal of antiepileptic medication may precipitate status epilepticus.

The therapeutic efficacy of a dosage regimen takes several days before it can be assessed.

Use in pregnancy: Recent reports strongly suggest an association between the use of anticonvulsant drugs by women with epilepsy and an elevated incidence of birth defects in children born to these women. Reference has been made to primidone in several cases in which it was used *in combination* with other anticonvulsants; but its teratogenicity has not been conclusively demonstrated. The possibility exists that other factors, *e.g.*, genetic factors or the epileptic condition, may contribute to the higher incidence of birth defects. The data also indicate that the great majority of mothers receiving anticonvulsant medication deliver normal infants.

Anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and risk to both mother and the unborn child.

When the nature, frequency, and severity of the seizures do not pose a clear threat to the patient, good medical practice requires that the physician weigh the expected therapeutic benefit of anticonvulsant therapy against possible risk on an individual basis.

Neonatal hemorrhage, with a coagulation defect resembling vitamin K deficiency, has been described in newborns whose mothers were taking primidone and other anticonvulsants. Pregnant women under anticonvulsant therapy should receive prophylactic vitamin K_1 therapy for one month prior to, and during, delivery.

The physician should weigh all of the foregoing considerations when treating and counseling epileptic women of childbearing potential.

PRECAUTIONS: The total daily dosage should not exceed 2 Gm. Since MYSOLINE therapy generally extends over prolonged periods, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

In nursing mothers: There is evidence that in mothers treated with primidone, the drug appears in the milk in substantial quantities. Since tests for the presence of primidone in biological fluids are too complex to be carried out in the average clinical laboratory, it is suggested that the presence of undue somnolence and drowsiness in nursing newborns of MYSOLINE-treated mothers be taken as an indication that nursing should be discontinued.

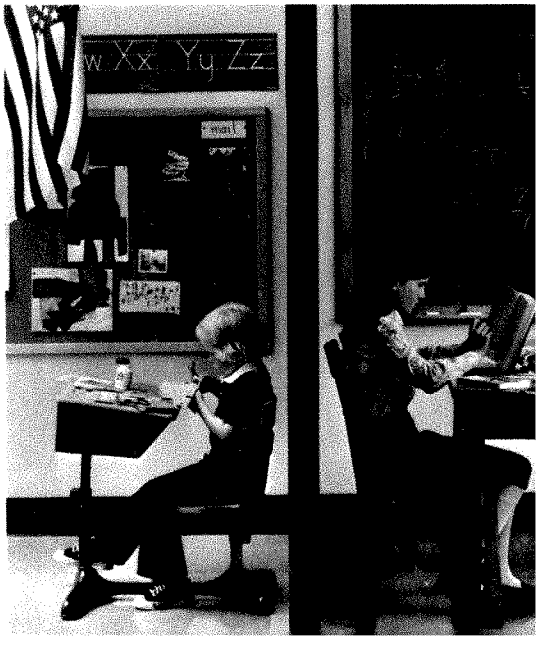
ADVERSE REACTIONS: The most frequently occurring early side effects are ataxia and vertigo. These tend to disappear with continued therapy, or with reduction of initial dosage. Occasionally, the following have been reported: nausea, anorexia, vomiting, fatigue, hyperirritability, emotional disturbances, sexual impotency, diplopia, nystagmus, drowsiness, and morbilliform skin eruptions. Occasionally, persistent or severe side effects may necessitate withdrawal of the drug. Megaloblastic anemia may occur as a rare idiosyncrasy to MYSOLINE and to other anticonvulsants. The anemia responds to folic acid, 15 mg. daily, without necessity of discontinuing medication.

DOSAGE AND ADMINISTRATION: The average adult dose is 0.75 to 1.5 Gm. per day. The initial dose is 250 mg. Increments of 250 mg. are added, usually at weekly intervals, to tolerance, or therapeutic effectiveness, up to daily doses not exceeding 2.0 Gm. A typical dosage schedule for the introduction of MYSOLINE (primidone) is as follows:

Adults and Children Over 8 Years of Age

1st Week 250 mg. daily at bedtime	*2nd Week* 250 mg. b.i.d.
3rd Week 250 mg. t.i.d.	*4th Week* 250 mg. q.i.d.

In children under 8 years of age, maintenance levels are established by a similar schedule, but at one-half the adult dosage. It is best to begin with 125 mg., with gradual weekly increases of 125 mg. a day, to a daily total usually between 500 mg. and 750 mg.



In patients already receiving other anticonvulsants: MYSOLINE should be gradually increased as dosage of the other drug(s) is maintained or gradually decreased. This regimen should be continued until satisfactory dosage level is achieved for combination, or the other medication is completely withdrawn. When therapy with this product alone is the objective, the transition should not be completed in less than two weeks.

MYSOLINE 50 mg. Tablet can be used to practical advantage when small fractional adjustments (upward or downward) may be required, as in the following circumstances:

- for initiation of combination therapy
- during "transfer" therapy
- for added protection in periods of stress or stressful situations that are likely to precipitate seizures (menstruation, allergic episodes, holidays, etc.)

HOW SUPPLIED: MYSOLINE *Tablets*—No. 430—Each tablet contains 250 mg. of primidone (scored), in bottles of 100 and 1,000. Also in unit dose package of 100. No. 431—Each tablet contains 50 mg. of primidone (scored), in bottles of 100 and 500. MYSOLINE *Suspension*—No. 3850—Each 5 cc. (teaspoonful) contains 250 mg. of primidone, in bottles of 8 fluid-ounces.

FIVE YEARS OF CLINICAL EFFICACY HAVE SHOWN...

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

MAY BE AN APPROPRIATE CHOICE FOR YOUR NEXT PATIENT WITH CLINICAL DEPRESSION/ANXIETY

See Brief Summary on last page of advertisement for information on adverse reactions, contraindications, warnings and precautions.

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and
ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

Proved efficacy in the treatment of clinical depression/anxiety

In the five years since its introduction, Sinequan (doxepin HCl) has objectively demonstrated its value in the treatment of clinical depression/anxiety. Clinical studies have shown Sinequan to be unsurpassed in effectiveness when compared to other tricyclic antidepressants.

In addition, Sinequan may offer certain advantages not generally seen with some other drugs of its class:

Marked antianxiety activity

In addition to its significant antidepressant activity, which is usually seen two to three weeks after initiation of therapy, Sinequan possesses marked antianxiety activity.

In double-blind comparisons between doxepin and amitriptyline,[1-3] the antidepressant effects of both drugs were comparable; however, more notable antianxiety effects were seen with doxepin. Superior antianxiety activity was reported among depressed patients treated in a crisis intervention clinic.[4]

Prompt sedative activity

Of the tricyclic antidepressants, Sinequan has been found to have one of the most prominent sedative effects.[5] This sedative property can be taken advantage of by administering the major portion of the daily dose *h.s.* Since clinically depressed/anxious patients frequently have accompanying sleep disturbances, this may be a valuable benefit.

Generally does not affect the activity of guanethidine at usual clinical doses[6]

"A new tricyclic antidepressant, doxepin, was evaluated for its ability to block the amine uptake mechanisms of the peripheral adrenergic neuron and blood platelet in man. At low doses, there was no evidence of inhibition of the amine pump." At clinical dosages up to 150 mg. per day, Sinequan can be given to man concomitantly with guanethidine and related compounds without blocking the antihypertensive effect.[6]

Cardiovascular side effects reported infrequently

In a series of double-blind comparative studies, 1706 doxepin-treated patients were evaluated for side effects. Incidence of tachycardia was associated with only 45 (2.6%) clinically depressed/anxious patients.[3]

SINEQUAN®
DOXEPIN HCl

100-mg., 50-mg., 25-mg. Capsules and
ORAL CONCENTRATE 10 mg./ml., 120-ml. (4-oz.) bottles

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, paresthesias, ataxia, and extrapyramidal symptoms.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, facial edema, photosensitization, pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, and anorexia have been reported. (See anticholinergic effects).

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice and alopecia have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, a starting dose of 25 mg. t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg./day to 150 mg./day.

In more severely ill patients an initial dose of 50 mg. t.i.d. may be required with subsequent gradual increase to 300 mg./day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg./day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg./day.

As an alternative regimen, the total daily dosage, up to 150 mg., may be given on a once-a-day schedule without loss of effectiveness. This dose may be given at bedtime.

Anti-anxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.

Supply. Available as capsules containing doxepin HCl equivalent to 10 mg., 25 mg., 50 mg., and 100 mg. of doxepin in bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). SINEQUAN (doxepin HCl) 25 mg. and 50 mg. also available in bottles of 5000. SINEQUAN Oral Concentrate (10 mg./ml.) is available in 120 ml. bottles with an accompanying dropper calibrated at 5 mg., 10 mg., 15 mg., 20 mg., and 25 mg. SINEQUAN Oral Concentrate should be diluted with approximately 120 ml. of water or orange juice prior to administration.

More detailed professional information available on request.

In clinically significant depression

TABLETS, 5 mg and 10 mg

Vivactil®*

(Protriptyline HCl | MSD)

***When you want an antidepressant that is characteristically nonsedating for the patient under close medical supervision (Symptoms such as anxiety or agitation may be aggravated.)**

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information please see following page.

In clinically significant depression

TABLETS, 5 mg and 10 mg

Vivactil®

(Protriptyline HCl | MSD)

Contraindications: Known hypersensitivity; acute recovery phase following myocardial infarction. Should not be given concomitantly with an MAOI; hyperpyretic crises, severe convulsions, and deaths have occurred in patients receiving tricyclic antidepressant and MAOI drugs simultaneously. When it is desired to substitute protriptyline HCl for an MAOI, a minimum of 14 days should be allowed to elapse after the latter is discontinued. Protriptyline HCl should then be initiated cautiously with gradual increase in dosage until optimum response is achieved.

Warnings: May block the antihypertensive effect of guanethidine or similarly acting compounds. May impair mental and/or physical abilities required for the performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Should be used with caution in patients with a history of seizures and, because of its autonomic activity, in patients with a tendency to urinary retention or increased intraocular tension.

Tachycardia and postural hypotension may occur more frequently than with other antidepressant drugs. Should be used with caution in elderly patients and patients with cardiovascular disorders; such patients should be observed closely because of the tendency of the drug to produce tachycardia, hypotension, arrhythmias, and prolongation of the conduction time. Myocardial infarction and stroke have occurred with drugs of this class. On rare occasions, hyperthyroid patients or those receiving thyroid medication may develop arrhythmias when this drug is given.

Usage in Children: Not recommended for use in children because safety and effectiveness in the pediatric age group have not been established.

Usage in Pregnancy: Safe use in pregnancy and lactation has not been established; therefore, use in pregnant women, nursing mothers, or women who may become pregnant requires that possible benefits be weighed against possible hazards to mother and child.

Precautions: When protriptyline HCl is used to treat the depressive component of schizophrenia, psychotic symptoms may be aggravated; likewise, in manic-depressive psychosis, depressed patients may experience a shift toward the manic phase; paranoid delusions, with or without associated hostility, may be exaggerated. In any of these circumstances, it may be advisable to reduce the dose of protriptyline HCl or to use a major tranquilizing drug concurrently. Symptoms, such as anxiety or agitation, may be aggravated in overactive or agitated patients.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. May enhance response to alcohol and effects of barbiturates and other CNS depressants. Possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have access to large quantities of the drug. Concurrent administration with electroshock therapy may increase hazards of therapy; such treatment should be limited to patients for whom it is essential. Discontinue drug several days before elective surgery, if possible. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions which have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when protriptyline HCl is administered. Protriptyline HCl is more likely to aggravate agitation and anxiety and produce cardiovascular reactions such as tachycardia and hypotension.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions, anxiety, restlessness, agitation; insomnia, panic, and nightmares; hypomania; exacerbation of psychosis.

Neurological: numbness, tingling, and paresthesias of extremities; incoordination, ataxia, tremors, peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns, tinnitus.

Anticholinergic: dry mouth and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of the urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (general, or of face and tongue), drug fever.

Hematologic: bone marrow depression; agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia.

Gastrointestinal: nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of other tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets, containing 5 mg and 10 mg protriptyline HCl each, in single-unit packages of 100 and bottles of 100 and 1000.

For more detailed information, consult your MSD representative or see full prescribing information.

CHALLENGING OPPORTUNITIES FOR PSYCHIATRISTS

Salary: $28,877 - $38,375
(dependent on qualifications)

Immediate opening for psychiatrists seeking a challenge in developing and implementing a comprehensive, interdisciplinary treatment program for a modern, community-oriented psychiatric center. Elmira Psychiatric Center is an innovative model for the type of client-centered mental health facility which serves as the hub of an active, well-coordinated system of psychiatric services. With satellite programs in adjacent Steuben and Schuyler Counties, the Center strives to meet the needs of nearly 250,000 population at risk. We are presently expanding our program to include inpatient and extended day treatment for children and geriatric clients.

Elmira is located in the beautiful Finger Lakes Region of Western New York, an area offering a year-round variety of sports and recreational activities. Ten colleges, including Cornell University, are within commuting distance. Elmira and its neighboring communities take pride in their good schools, excellent shopping areas, and pleasant pastoral surroundings. Syracuse and Rochester are located approximately two hours away.

We invite your participation in this institution. For more information please write to Director
Elmira Psychiatric Center
P. O. Box 1011
Elmira, NY 14902

Brown University Program in Medicine

is seeking a Chairman for the Section of Psychiatry and Human Behavior and Psychiatrist in Chief for the Butler Hospital. Inquiries and applications with curricula vitae should be addressed to Dr. Leo Stern, Chairman, Psychiatry Search Committee, Section of Reproductive and Developmental Medicine, Women & Infants Hospital, 50 Maude Street, Providence, Rhode Island 02908. Both Brown University and Butler Hospital are equal opportunity employers.

ROCHE

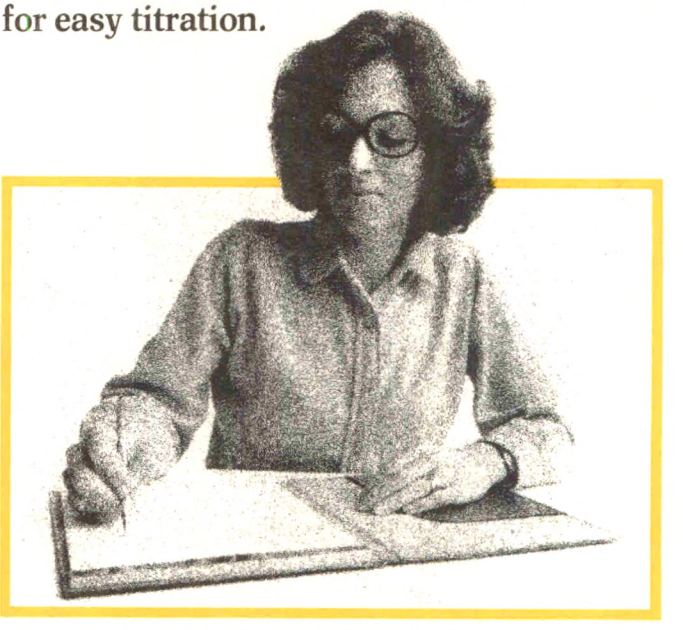
Introducing

The unforgettable antidepressant

Endep™ 75 mg

amitriptyline HCl / Roche

Here's what makes it unforgettable



Patients are more likely to remember the single bedtime dosage of Endep (amitriptyline HCl).

You'll remember 1 or 2 tablets *h.s.*, because fewer forgotten doses produce a more consistent clinical effect, and because it is the only tricyclic antidepressant scored for easy titration.

Patients will also remember family/interpersonal relationships that they have forgotten or neglected.

In three or four weeks patients will usually remember how well they used to feel.

Endep™ 75 mg

amitriptyline HCl/Roche

The antidepressant you can prescribe at night to work all day

Before prescribing, please consult complete product information, a summary of which appears on the following page.

Introducing Endep™

amitriptyline HCl/Roche

The antidepressant you can prescribe at night to work all day

10-mg scored tablets | **25-mg** scored tablets | **50-mg** scored tablets | **75-mg** scored tablets

■ Endep (amitriptyline HCl), in responsive patients, lifts mood and relieves symptoms such as anorexia, loss of interest, inability to concentrate, decreased libido or GI disturbances, often within three or four weeks after starting therapy.

■ Endep usually relieves accompanying sleep disturbances, particularly early in the treatment regimen.

■ All four dosage strengths are scored for greater flexibility and convenience in titration.

■ The 75-mg *h.s.* dose minimizes skipped doses, maximizes patient acceptance and compliance.

■ Specifying Endep/Roche assures quality plus potential economy.

Important Considerations

Should not be given concomitantly with an MAO inhibitor.

Not recommended for use during the acute recovery phase following myocardial infarction.

Contraindicated in patients with hypersensitivity to amitriptyline.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depression) and depression accompanied by anxiety.

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh potential benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia. purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Dosage: Initiate at low levels; increase gradually, watching for signs of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier. *Initial Adult Dosage:* Outpatients – 25 mg t.i.d.; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate – 50 to 100 mg h.s., gradually increasing h.s. dose up to 150 mg/day. Hospitalized Patients – Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day. *Adolescent and Elderly Patients:* In general, 10 mg t.i.d. with 20 mg h.s. may be satisfactory for those who do not tolerate higher doses. *Maintenance Dosage:* With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg b.i.d. to q.i.d., or 10 mg q.i.d. Continue maintenance therapy 3 months or longer to avoid relapse.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

Supplied: 10-mg, 25-mg, 50-mg and 75-mg scored tablets – bottles of 100 and 500; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg), available singly and in trays of 10.

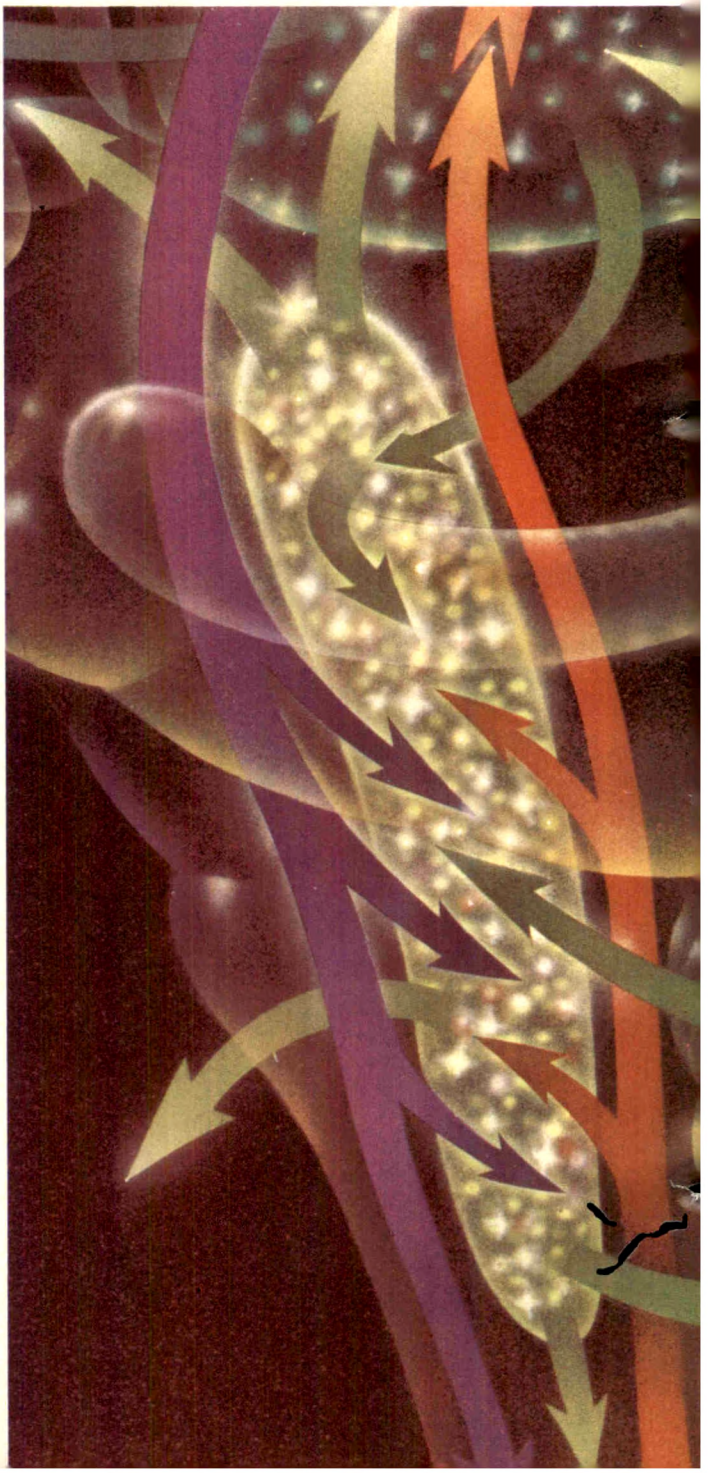
Whether your schizophrenic patient is hospitalized or ambulatory, he may benefit from a different chemical modality

MOBAN®
(molindone HCl)

acts on the RAS with low incidence of adverse effects

EEG studies show that MOBAN® exerts its effect on the ascending reticular activating system. This often helps to encourage increased social participation, receptivity and communication in schizophrenic patients.

Artist's representation of the reticular activating system, with neuronal activity passing on to cortical and subcortical structures.



for a chemical difference in treating the schizophrenias

MOBAN®
(molindone HCl)

- generally minimizes drowsiness to help produce improved functioning
  1) to hasten the discharge of hospitalized patients
  2) to keep ambulatory patients at home or on the job

- tranquilizes without muscle relaxant or incoordinating effect

- acts to alleviate target symptoms or reduce their severity
  1) in acute patients, some symptomatic improvement evident in a few days
  2) in chronic patients, symptomatic improvement may not be evident until 2-4 weeks
  3) maximum benefits attained by end of third month (continued maintenance therapy as required)

In early clinical trials, of 425 patients studied, 72% showed overall global improvement in double-blind studies.*

communication

there's something different about

MOBAN®
(molindone HCl)

Please see last page of advertisement for full prescribing information.

Whenever your patient may benefit from less sedation, more activation– MOBAN® (molindone HCl)

CLINICAL EXPECTATIONS FROM MOBAN® (molindone HCl)

The following has been compiled from clinical and field reports, according to the best available information to date.

activation The pattern that has emerged for MOBAN®. This may conflict with usual nursing procedure on the ward at first, but is usually an early indication of improvement.

agitated patient These patients may require a more rapid increase of dose to control symptoms. (Caution should be exercised where increased activity may be harmful.)

amenorrhea Has rarely developed with MOBAN®, as it has with other antipsychotics. Amenorrheic patients have returned to normal menses when switched to MOBAN® from other antipsychotics. Initial periods may be somewhat heavy and prolonged, but soon stabilize to normal.

Endo Laboratories, Inc.
Subsidiary of E.I. du Pont de Nemours & Co. (Inc.)
Garden City, N.Y. 11530
DUPONT

dopamine blockage Demonstrated in animals.

drug interaction None reported to date with commonly co-prescribed drugs. Potentiation of drugs administered concurrently with MOBAN® has not been reported. Additionally, animal studies have not shown increased toxicity when MOBAN® is given concurrently with representative members of three classes of drugs *(i.e.,* barbiturates, chloral hydrate and antiparkinson drugs).

duration of action Exceeding 24 hours.

euphoria Experienced by some patients.

extrapyramidal symptoms Similar to other antipsychotics, but easily controlled. Akathisia most frequently reported, dystonia rare.

insomnia If it occurs, decrease daytime dosage, increase evening dosage.

laboratory values Within normal limits.

lactation A rarity with MOBAN®

lenticular opacity None reported to date. A decrease noted after switching to MOBAN®.

libido No decrease in libido. An increase noted in some patients.

liver dysfunction None reported to date.

peak blood levels Unmetabolized drug peaks at 1 hour, pharmacologic effect persists for 24-36 hours.

relative milligram equivalency MOBAN® is to chlorpromazine 1:6.

sedation MOBAN® may produce transient sedation (1-2 weeks) and has seldom had a prolonged sedative effect.

side effects Seldom does MOBAN® cause the peripheral and endocrine effects produced by the aliphatic and piperidine phenothiazines. MOBAN® may cause extrapyramidal reactions, transient initial drowsiness, fatigue, dizziness, mild hypotension, constipation, weight changes. Other potential adverse reactions described in the accompanying prescribing information.

skin pigmentation None reported to date.

switching Allow time for the previous neuroleptic's effect to wear off and the difference in side effects; *e.g.,* amenorrhea versus normal flow. Also allow for difference in strength until MOBAN® reaches therapeutic dose.

tardive dyskinesia None reported to date.

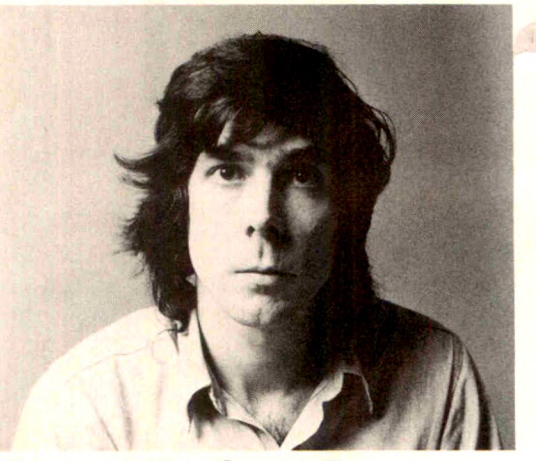
tolerance None reported to date.

weight change Some obese patients lost large amounts of weight while eating normally. Limited weight gain was noted in other patients.

a dihydroindolone chemically distinct from phenothiazines, thioxanthenes, butyrophenones

MOBAN®
(molindone HCl)

to help control the manifestations of schizophrenia

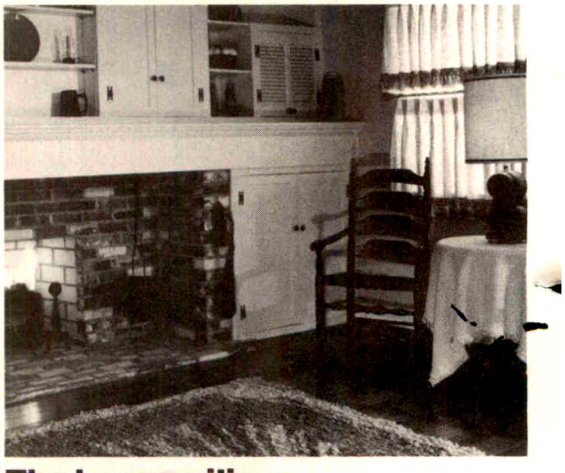


Please see last page of advertisement for full prescribing information.

When to use MOBAN® (molindone HCl)

- for new patients, acute or chronic
- for hospitalized patients, those in hospital clinics and community mental health centers, or those at home or on the job
- when poor results are obtained with other antipsychotics
- when certain undesirable side effects occur with other antipsychotics
- as a replacement for polypharmacy, thus reducing cost, custodial care, risk of side effects
- if patient is refractory to other treatment (after diagnostic reappraisal)

THE IN-HOSPITAL PATIENT.

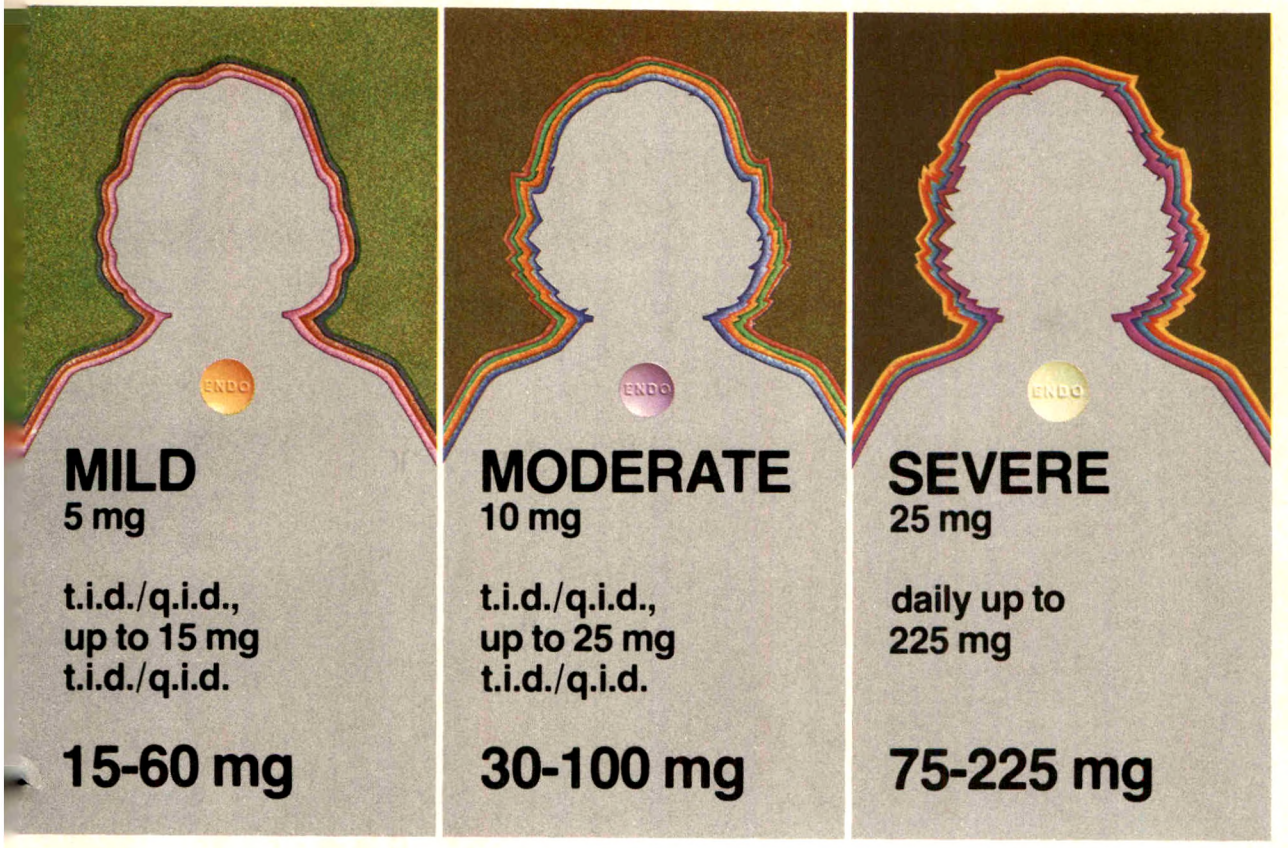


Activation may make the patient more productive. Sedation may increase the patient's baseline anergic vegetative qualities. An activating effect may not benefit every patient.

The neuroleptic syndrome:
anergic vegetative qualities increase.

THE AT-HOME PATIENT.

The hope is that this patient can not only maintain a home but hold a job. That will probably require daytime alertness. For many outpatients, sedation may impair efficiency while activation might improve it.



The home milieu:
an end goal of schizophrenic therapy.

How to use MOBAN® (molindone HCl)

a wide range of dosage strength

MILD
5 mg

t.i.d./q.i.d., up to 15 mg t.i.d./q.i.d.

15-60 mg

MODERATE
10 mg

t.i.d./q.i.d., up to 25 mg t.i.d./q.i.d.

30-100 mg

SEVERE
25 mg

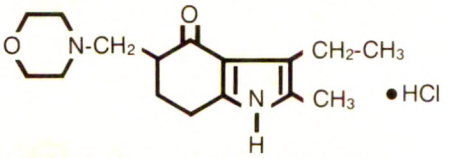
daily up to 225 mg

75-225 mg

Titrate for 1) therapeutic response and 2) minimal effective maintenance dose.

Use lower doses for the elderly and debilitated.

NOTE: Transient drowsiness may occur during the first 1-2 weeks.



MOBAN®
(molindone HCl)

a chemically distinct treatment modality for the schizophrenias that helps to encourage greater social participation, receptivity, communication

Please see next page for full prescribing information.

MOBAN®
(molindone HCl)

DESCRIPTION MOBAN® (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.
MOBAN® is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4(5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

MOLINDONE HYDROCHLORIDE

ACTIONS MOBAN® (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, MOBAN® antagonizes the depression caused by the tranquilizing agent tetrabenazine.
In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, MOBAN® exerts its effect on the ascending reticular activating system.
Human metabolic studies show MOBAN® to reach peak blood levels within one hour after oral administration.

INDICATIONS MOBAN® (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS MOBAN® (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS Usage in Pregnancy Studies in the pregnant patient have not been carried out. Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in these patients.

Nursing Mothers Data is not available on the content of MOBAN® (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children Use of MOBAN® (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS Some patients receiving MOBAN® (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.
Increased activity has been noted in patients receiving MOBAN®. Caution should be exercised where increased activity may be harmful.

ADVERSE REACTIONS Transient initial drowsiness was noted most frequently. Noted less frequently were Parkinsonian reactions (akinesia characterized by rigidity, immobility and reduction of voluntary movement and tremor), akathisia, restlessness, insomnia, depression, feeling of dizziness, blurred vision, hyperactivity, euphoria, dry mouth, headache, nausea and tachycardia. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.
Others which were observed included weight gain, weight loss, suicidal thinking, postural hypotension, initial heavy menses, amenorrhea, lactation, rash, spasticity, dystonia, akinesia, oculogyric crisis, gastrointestinal upset, increased libido, leukopenia, and nonspecific EKG changes.

ADVERSE REACTIONS NOTED WITH OTHER ANTIPSYCHOTIC AGENTS
The following adverse reactions have been observed with phenothiazine antipsychotic drugs. MOBAN® (molindone hydrochloride) differs chemically and to some degree pharmacologically from phenothiazines, but the possibility that similar adverse reactions may occur with MOBAN® (molindone hydrochloride) should be kept in mind.

Drowsiness Usually mild to moderate, may occur, particularly during the first or second week, after which it generally disappears. If troublesome, dosage may be lowered.

Jaundice Over-all incidence has been low, regardless of indication or dosage. Most investigators conclude it is a sensitivity reaction. Most cases occur between the second and fourth weeks of therapy. The clinical picture resembles infectious hepatitis, with laboratory features of obstructive jaundice, rather than those of parenchymal damage. It is usually promptly reversible on withdrawal of the medication; however, chronic jaundice has been reported. There is no conclusive evidence that pre-existing liver disease makes patients more susceptible to jaundice. Alcoholics with cirrhosis have been successfully treated with phenothiazine, without complications. Nevertheless, the medication should be used cautiously in patients with liver disease. Patients who have experienced jaundice with a phenothiazine should not, if possible, be re-exposed to phenothiazines.
If fever with grippe-like symptoms occurs, test for increased bilirubin or for bile in urine. If tests are positive, stop treatment.
Liver function tests in jaundice induced by the drug may mimic extrahepatic obstruction; withhold exploratory laparotomy until extrahepatic obstruction is confirmed.

Hematological Disorders Including agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura, and pancytopenia, though rare, have been reported.

Agranulocytosis Observe patients regularly for sudden appearance of sore throat or other signs of infection. If white blood counts and differential smears indicate cellular depression, stop treatment and start antibiotic and other suitable therapy.
Most cases have occurred between the 4th and 10th weeks of therapy; patients should be watched closely during that period.
Moderate suppression of white blood cells is not an indication for stopping treatment unless accompanied by the symptoms described above.

Cardiovascular: Hypotensive Effects Postural hypotension, simple tachycardia, momentary fainting and dizziness may occur after the first injection; occasionally after subsequent injections; rarely after the first oral dose. Usually recovery is spontaneous and symptoms disappear within ½ to 2 hours. Occasionally, these effects may be more severe and prolonged, producing a shock-like condition.

EKG Changes Particularly nonspecific, usually reversible Q and T wave distortions—have been observed in some patients receiving phenothiazine tranquilizers. Their relationship to myocardial damage has not been confirmed.
Note: sudden death, apparently due to cardiac arrest, has been reported, but there is not sufficient evidence to establish a relationship between such deaths and the administration of the drug.

C.N.S. Effects: Neuromuscular (Extrapyramidal) Reactions Closely resembling parkinsonism, and motor restlessness have occurred most frequently in psychiatric patients receiving high dosages. Dystonic reactions have been reported occasionally. Such symptoms usually disappear soon after dosage is lowered, the drug temporarily withdrawn, and/or concomitant administration of an antiparkinsonism agent. (Note: Levodopa has not been found effective in relief of these neuromuscular reactions.) In severe cases suitable supportive measures such as maintaining a clear airway and adequate hydration should be used. When phenothiazine is reinstituted, it should be at a lower dosage.
Hyperreflexia has been reported in the newborn.

Persistent Tardive Dyskinesia As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.
There is no known effective treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.
It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

Adverse Behavioral Effects Psychotic symptoms and catatonic-like states have been reported rarely.

Other C.N.S. Effects Cerebral edema has been reported.
Convulsive seizures (petit mal and grand mal) have been reported, particularly in patients with EEG abnormalities or history of such disorders.
Abnormality of the cerebrospinal fluid proteins has also been reported.

Allergic Reactions Of a mild urticarial type of photosensitivity are seen. Avoid undue exposure to sun. More severe reactions, including exfoliative dermatitis, have been reported occasionally.

Endocrine Disorders Lactation and moderate breast engorgement may occur in females on large doses. If persistent, lower dosage or withdraw drug. False positive pregnancy tests have been reported, but are less likely to occur when a serum test is used. Amenorrhea and gynecomastia have also been reported. Hyperglycemia, hypoglycemia and glycosuria have been reported.

Autonomic Reactions Occasional dry mouth; nasal congestion; constipation; adynamic ileus; urinary retention; miosis and mydriasis.

Special Considerations in Long-Term Therapy Skin pigmentation and ocular changes have occurred in some patients taking substantial doses of phenothiazines, for prolonged periods.

Skin Pigmentation Rare instances of skin pigmentation have been observed in hospitalized mental patients, primarily females who have received the drug usually for three years or more in higher dosages. The pigmentary changes, restricted to exposed areas of the body, range from an almost imperceptible darkening of the skin to a slate gray color, sometimes with a violet hue. Histological examination reveals a pigment, chiefly in the dermis, which is probably a melanin-like complex. The pigmentation may fade following discontinuance of the drug.

Ocular Changes Ocular changes have occurred more frequently than skin pigmentation and have been observed both in pigmented and nonpigmented patients receiving phenothiazines, usually for two years or more. Eye changes are characterized by deposition of fine particulate matter in the lens and cornea. In more advanced cases, star-shaped opacities have also been observed in the anterior portion of the lens. The nature of the eye deposits has not yet been determined. A small number of patients with more severe ocular changes have had some visual impairment. In addition to these corneal and lenticular changes, epithelial keratopathy and pigmentary retinopathy have been reported. Reports suggest that the eye lesions may regress after withdrawal of the drug.
Since the occurrence of eye changes seems to be related to dosage levels and/or duration of therapy, it is suggested that long-term patients on moderate to high dosage levels have periodic ocular examinations.

Etiology The etiology of both of these reactions is not clear, but exposure to light, along with dosage/duration of therapy, appears to be the most significant factor. If either of these reactions is observed, the physician should weigh the benefits of continued therapy against the possible risks and, on the merits of the individual case, determine whether or not to continue present therapy, lower the dosage, or withdraw the drug.

Other Adverse Reactions Mild fever may occur after large I.M. doses. Hyperpyrexia has been reported. Increases in appetite and weight sometimes occur. Peripheral edema and a systemic lupus erythematosus-like syndrome have been reported.
Note: There have been occasional reports of sudden death in patients receiving phenothiazines. In some cases, the cause appeared to be asphyxia due to failure of the cough reflex. In others, the cause could not be determined. There is not sufficient evidence to establish a relationship between such deaths and the administration of phenothiazines.

DOSAGE AND ADMINISTRATION Initial and maintenance doses of MOBAN® (molindone hydrochloride) should be individualized, and the minimal effective dose should be employed. Elderly and debilitated patients should be started on lower dosage.

Dosage schedule, based on severity of symptomatology
1. Mild—5 mg three or four times a day; an increase to 15 mg three or four times a day may be required.
2. Moderate—10 mg three or four times a day; an increase to 25 mg three or four times a day may be required.
3. Severe—daily dosage as high as 225 mg may be required.

DRUG INTERACTIONS Potentiation of drugs administered concurrently with MOBAN® (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when MOBAN® is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE Symptomatic, supportive therapy should be the rule.
Gastric lavage is indicated for the reduction of absorption of MOBAN® (molindone hydrochloride) which is freely soluble in water.
Since the absorption of MOBAN® (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.
Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by MOBAN® in animals, this blocking effect has not been determined in humans.
A significant increase in the rate of removal of unmetabolized MOBAN® from the body by forced diuresis, peritoneal or renal dialysis would **not** be expected. (Only 2% of a single ingested dose of MOBAN® is excreted unmetabolized in the urine.) However, poor response of the patient may justify use of these procedures. While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized MOBAN® in feces is less than 1%.
Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents, (i.e., Artane*, Cogentin*, Akineton*).

HOW SUPPLIED As tablets in bottles of 100 and 1,000 with potencies and colors as follows: 5 mg orange, 10 mg lavender, 25 mg light green.

*Benadryl —Trademark, Parke Davis and Co.
*Artane —Trademark, Lederle Laboratories
*Cogentin —Trademark, Merck Sharp & Dohme
*Akineton—Trademark, Knoll Pharmaceutical Co.

'STELAZINE' PROVIDES EFFECTIVE CONTROL OF HALLUCINATIONS, DELUSIONS, ANXIETY AND OTHER PSYCHOTIC SYMPTOMS.
BECAUSE IT APPEARS TO HAVE AN ACTIVATING EFFECT, 'STELAZINE' IS ESPECIALLY USEFUL IN WITHDRAWN, APATHETIC OR DETACHED PATIENTS.

- CONTROLS PSYCHOTIC SYMPTOMS
- SELDOM CAUSES EXCESSIVE SEDATION
- CONVENIENT B.I.D. DOSAGE

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F Co.) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only) 10 mg./ml.

Register Now for APA Self-Assessment Program

by May 31, 1976

The APA announces availability of the third Psychiatric Knowledge and Skills Self-Assessment Program. Program registration will be accepted through May 31, 1976; program materials will be mailed to registrants on June 15, 1976; answer materials should be returned for central scoring by September 10, 1976; and performance data will be mailed on November 15th.

PKSAP-III addresses many areas of daily practice, cognitive and clinical, to stimulate individual learning and motivate each participant to discuss new developments and emerging issues with colleagues. Absolute confidentiality will be maintained in regard to individual results, which will be reported directly and only to the participant.

A Bulletin of Information, an indepth description of the Program, will be mailed to each APA member. However, you may register by completing the form below and submitting it with the appropriate fee to Educational Testing Service, Princeton, New Jersey 08540.

The American Journal of Psychiatry, formerly *The American Journal of Insanity*, is published monthly by the American Psychiatric Association. Editorial office: 1700 Eighteenth Street, N.W., Washington, D.C. 20009; telephone (202) 232-7878.

Subscriptions: U.S. $18.00 per year, Canada and South America $19.00, other foreign $22.00; single issues: $2.25 plus postage.

Business communications and changes of address from APA members should be directed to the Division of Membership Services and Studies. Communications from non-member subscribers should be directed to the Circulation Department, American Psychiatric Association, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Four to six weeks advance notice is required for changes of address.

Advertising representatives: Steven K. Herlitz, Inc., 850 Third Avenue, New York, N.Y. 10022.

Type set by Bru-El Graphic, Inc., 5408 Port Royal Road, Springfield, Va. 22151.

Printed by Dartmouth Printing Co., 69 Lyme Road, Hanover, N.H. 03755.

Second class postage paid at Washington, D.C., and additional mailing offices.

Indexed in *Abstracts for Social Workers*, *Biological Abstracts*, *Chemical Abstracts*, *Cumulative Index to Nursing Literature*, *Excerpta Medica*, *Hospital Literature Index*, *Index Medicus*, *International Nursing Index*, *Nutrition Abstracts*, and *Psychological Abstracts*.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in duplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit two copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

Communications about a manuscript, by letter or telephone (202-232-7878), should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; in the case of other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, which is a copyrighted publication, the legal ownership of all parts of the paper, including any illustrations, passes from the author to the *Journal*. If an individual or organization wishes to reprint material published in the *Journal*, written permission must first be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Wash., D.C. 20009; there will usually be a charge for granting this permission.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not reflect the official attitude or position of the American Psychiatric Association or of the *Journal's* Editorial Board.

SPECIFICATIONS FOR MANUSCRIPTS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond (or other opaque) paper. All parts of the manuscript (including case reports, footnotes, references, etc.) should be double-spaced, with generous margins. Subheads should be inserted at reasonable intervals to aid in comprehension and to break the typographical monotony of lengthy texts. Abbreviations not easily recognized by the average reader should be explained.

Length. As a general rule the manuscript of a regular article should not exceed 10–12 typed pages, unless a special arrangement has been made with the Editor; Brief Communications should not exceed eight typed pages. Letters to the Editor should not exceed 500 words unless a special arrangement has been made with the Editor.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the co-author who has been designated to handle the galley proofs and reprint requests. The number of authors should preferably not exceed four, with other collaborators being acknowledged in a footnote.

Precis. A brief precis is included at the beginning of each article: 60–100 words for regular articles, 40–60 words for Brief Communications. The author may prepare the precis himself or ask that the *Journal* staff prepare it, in which case the author may make any necessary changes on the galley proofs.

Informed consent. Manuscripts that report the results of experimental investigation on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure had been fully explained.

References. References should be typed double-spaced on a separate sheet of paper, to be attached at the end of the manuscript. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below for books and journal articles; chapters in books will be treated as journal articles with regard to capitalization. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Titles and headings of any tables and figures should be sufficiently clear that the meaning of the data is understandable without reference to the text. See recent issues of the *Journal* for the general requirements of style.

Each table should be typed on a separate sheet, attached at the end of the manuscript. The data should be arranged so that columns of like material read down, not across.

A complete set of figures, preferably in the form of glossy prints, should accompany each of the two copies of the manuscript. Most figures will be reduced to about 3¼ inches in width, the column width of the *Journal*; all elements of a figure should be prepared to withstand this reduction. Graphs should be finished drawings not requiring further artwork. Authors are urged to engage the services of a professional in the preparation of figures. Authors may be required to meet the costs of any further artwork that must be done in the editorial office.

AUTHORS' CORRECTIONS

Galley proofs will be sent to the first-named author for corrections after the paper has been scheduled for publication; prompt return (preferably within 48 hours of receipt) is necessary to ensure publication in the assigned month. If an author expects to be away from his office for a long period of time after he has received the acceptance letter, he should inform the *Journal* office or arrange with a colleague to read the proofs. Authors are urged to keep changes on galleys to a minimum.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be attached to the galley proofs submitted to authors for correction. Reprints are usually mailed to authors about a month after publication of the article. Requests from others to order reprints should be directed to the Editor; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

THE AMERICAN PSYCHIATRIC ASSOCIATION

1700 Eighteenth Street, N.W., Washington, D.C. 20009

Released from symptoms of psychotic depression...

Productive again.

By helping to reduce the frequency and intensity of psychotic symptoms, Navane (thiothixene) often permits resumption of more normal, more productive living.

The antipsychotic effectiveness of Navane—with relatively little drowsiness—helps patients remain more active, more alert, better able to meet the ordinary demands of life.

Cardiovascular side effects such as hypotension and nonspecific EKG changes are relatively rare with Navane (thiothixene). Extrapyramidal symptoms have been reported, but are usually controlled by reduction in dosage and/or administration of antiparkinson drugs.

Once you've controlled acute psychosis or psychotic depression, some patients can be maintained on a simple once-a-day dose. This once-a-day regimen can reduce the risk of missed doses with no loss of efficacy.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals
New York, New York 10017

Navane®

(thiothixene) (thiothixene hydrochloride)

Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg/Concentrate 5 mg/ml

Once-a-day–to help control symptoms of psychosis

For prescribing information, including adverse reactions and contraindications please see following page of this advertisement.

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Actions. Navane is a psychotropic agent of the thioxanthene series. Navane possesses certain chemical and pharmacological similarities to the piperazine phenothiazines and differences from the aliphatic group of phenothiazines. Navane's mode of action has not been clearly established.

Indications. Navane is effective in the management of manifestations of psychotic disorders.

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy* – Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children—The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration – As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane. Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudoparkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leucocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution—For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate—In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor elevating action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg, of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

Three Treatment Centers

Three treatment centers provide individually prescribed programs of care, education, treatment and training for children, adolescents and adults with learning disabilities, neurological impairment, mental retardation or emotional disturbance.

Advantage: the availability of a **large, trained and experienced staff,** exchanging ideas and insights in a comprehensive program of supportive environment and individualized treatment.

Advantage: **geographically separated** to provide the proper residential milieu . . . yet near enough to benefit from the combined training and experience of a wide range of staff members.

The Oaks — A residential psychiatric treatment center for emotionally disturbed children and adolescents between the ages of six and 18. Coeducational, Austin. In addition, the Center provides a Short Term Adolescent Center and a six bed intensive care unit.

The San Marcos Treatment Center — a facility with three campuses designed for individuals with psychiatric, neurological, and intellectual difficulties who have evidenced a need for a 24-hour therapeutic milieu.

The Center offers a broad spectrum of services to both mentally retarded individuals and those with psychiatric disorders. In addition to a structured therapeutic environment, individual and group psychotherapy services are available to each resident. Clinical supervision and support services are provided by the Center psychiatrists.

The Ranch Treatment Center — located in the suburbs of Austin the Center provides both long-term and intermediate tenure services to multi-handicapped male adolescents and adults whose primary diagnostic classifications are in areas of mental retardation and mental illness. All residents receive program services which may permit their early discharge to the less restrictive settings of community-based programs.

Valium® (diazepam) Close-Up

Product information for psychiatrists

If your patient is taking one of these...

Primary medications

anticoagulants
antacids
cardiac glycosides
diuretics
vasodilators
anticholinergics

Psychotropics/CNS depressants

alcohol
phenothiazines
narcotics
barbiturates
hypnotics
MAO inhibitors
minor tranquilizers
antidepressants

Anticonvulsants

ROCHE

you should know this about Valium® (diazepam)

Valium is frequently used with most classes of these primary medications. Clinically significant drug interactions have not been reported to date.

Potentiation may occur with other CNS depressants. Careful consideration should be given to the pharmacology of these compounds when used concomitantly with Valium.

As with other agents which have anticonvulsant activity, the possibility of increase in frequency and/or severity of grand mal seizures may require an increase in dosage of standard anticonvulsants.

Valium® (diazepam) ℞

2-mg, 5-mg, 10-mg scored tablets

Before prescribing, please see following page for a summary of product information

Valium® (diazepam)

2-mg, 5-mg, 10-mg scored tablets

can relieve psychoneurotic anxiety and its associated depressive symptoms

Prompt, effective action. Valium works rapidly to relieve pronounced psychic tension in patients overreacting to stress and in psychoneurotic patients.

Wide margin of safety. Valium is generally well tolerated and in usual dosages rarely produces significant adverse reactions.

Dosage flexibility. Scored Valium 2-, 5-, 10-mg tablets give you dosage flexibility no tranquilizer capsule can match.

Before prescribing, please consult complete product information, a summary of which follows:

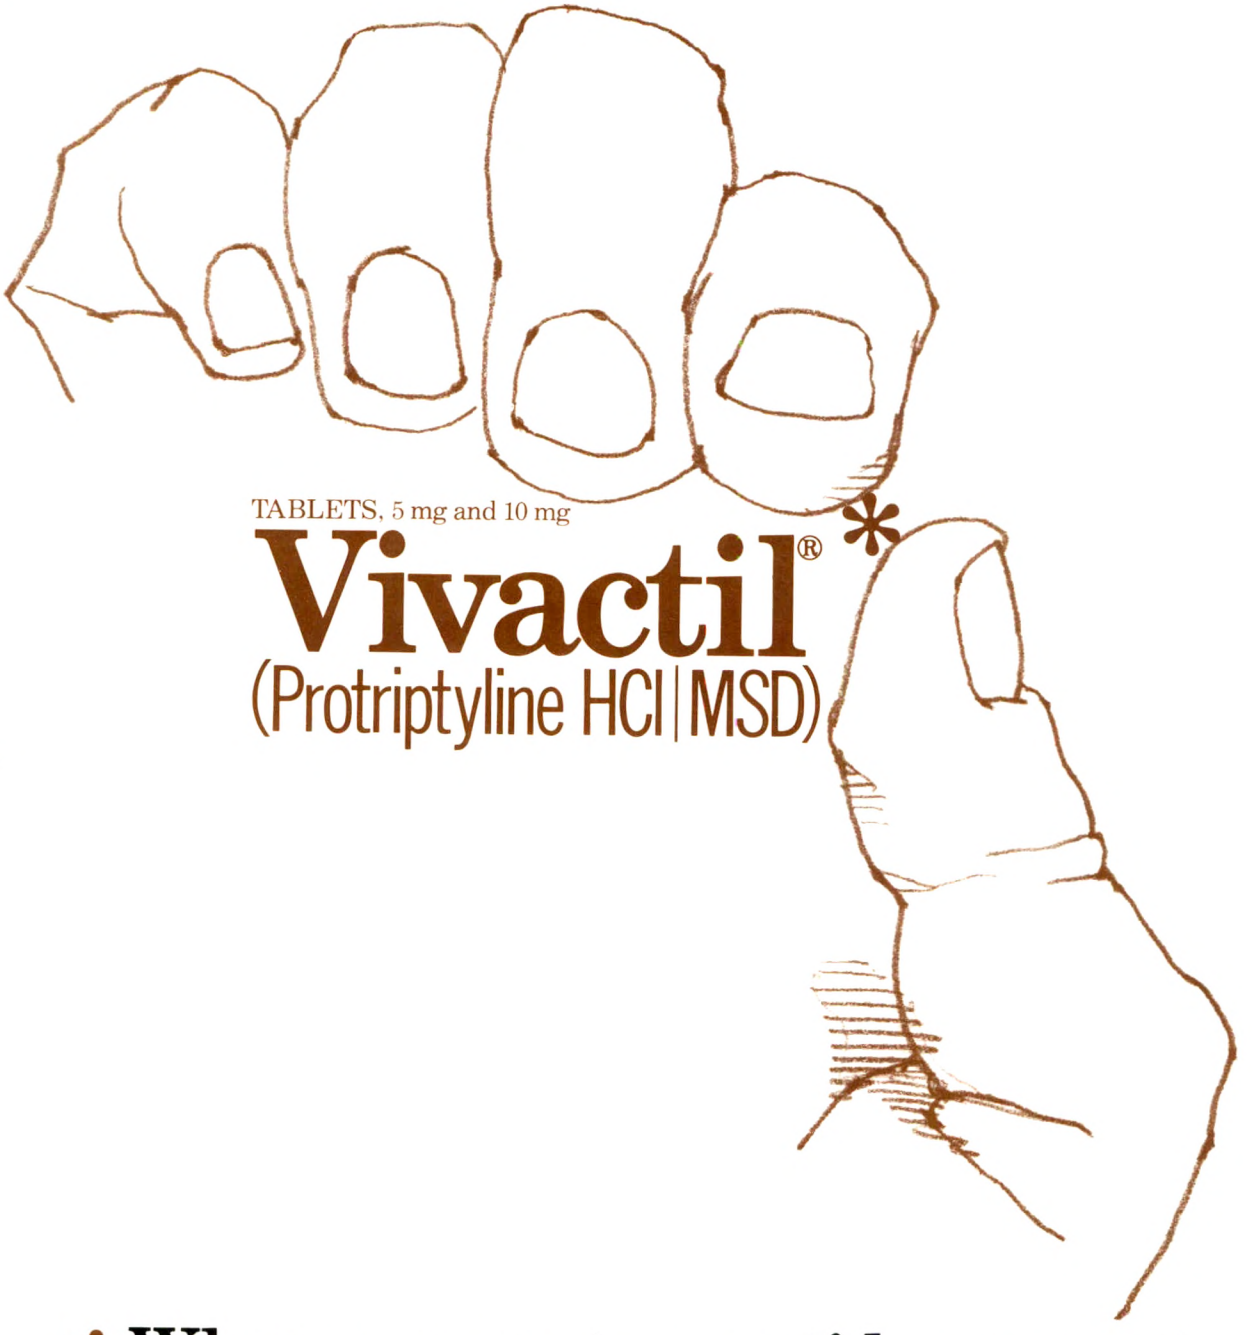
Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.



Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

In clinically significant depression

TABLETS, 5 mg and 10 mg

Vivactil®*

(Protriptyline HCl | MSD)

***When you want an antidepressant that is characteristically nonsedating for the patient under close medical supervision (Symptoms such as anxiety or agitation may be aggravated.)**

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information please see following page.

In clinically significant depression

TABLETS, 5 mg and 10 mg

Vivactil®

(Protriptyline HCl | MSD)

Contraindications: Known hypersensitivity; acute recovery phase following myocardial infarction. Should not be given concomitantly with an MAOI; hyperpyretic crises, severe convulsions, and deaths have occurred in patients receiving tricyclic antidepressant and MAOI drugs simultaneously. When it is desired to substitute protriptyline HCl for an MAOI, a minimum of 14 days should be allowed to elapse after the latter is discontinued. Protriptyline HCl should then be initiated cautiously with gradual increase in dosage until optimum response is achieved.

Warnings: May block the antihypertensive effect of guanethidine or similarly acting compounds. May impair mental and/or physical abilities required for the performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Should be used with caution in patients with a history of seizures and, because of its autonomic activity, in patients with a tendency to urinary retention or increased intraocular tension.

Tachycardia and postural hypotension may occur more frequently than with other antidepressant drugs. Should be used with caution in elderly patients and patients with cardiovascular disorders; such patients should be observed closely because of the tendency of the drug to produce tachycardia, hypotension, arrhythmias, and prolongation of the conduction time. Myocardial infarction and stroke have occurred with drugs of this class. On rare occasions, hyperthyroid patients or those receiving thyroid medication may develop arrhythmias when this drug is given.

Usage in Children: Not recommended for use in children because safety and effectiveness in the pediatric age group have not been established.

Usage in Pregnancy: Safe use in pregnancy and lactation has not been established; therefore, use in pregnant women, nursing mothers, or women who may become pregnant requires that possible benefits be weighed against possible hazards to mother and child.

Precautions: When protriptyline HCl is used to treat the depressive component of schizophrenia, psychotic symptoms may be aggravated; likewise, in manic-depressive psychosis, depressed patients may experience a shift toward the manic phase; paranoid delusions, with or without associated hostility, may be exaggerated. In any of these circumstances, it may be advisable to reduce the dose of protriptyline HCl or to use a major tranquilizing drug concurrently. Symptoms, such as anxiety or agitation, may be aggravated in overactive or agitated patients.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. May enhance response to alcohol and effects of barbiturates and other CNS depressants. Possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have access to large quantities of the drug. Concurrent administration with electroshock therapy may increase hazards of therapy; such treatment should be limited to patients for whom it is essential. Discontinue drug several days before elective surgery, if possible. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions which have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when protriptyline HCl is administered. Protriptyline HCl is more likely to aggravate agitation and anxiety and produce cardiovascular reactions such as tachycardia and hypotension.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions, anxiety, restlessness, agitation; insomnia, panic, and nightmares; hypomania; exacerbation of psychosis.

Neurological: numbness, tingling, and paresthesias of extremities; incoordination, ataxia, tremors, peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns, tinnitus.

Anticholinergic: dry mouth and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of the urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (general, or of face and tongue), drug fever.

Hematologic: bone marrow depression; agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia.

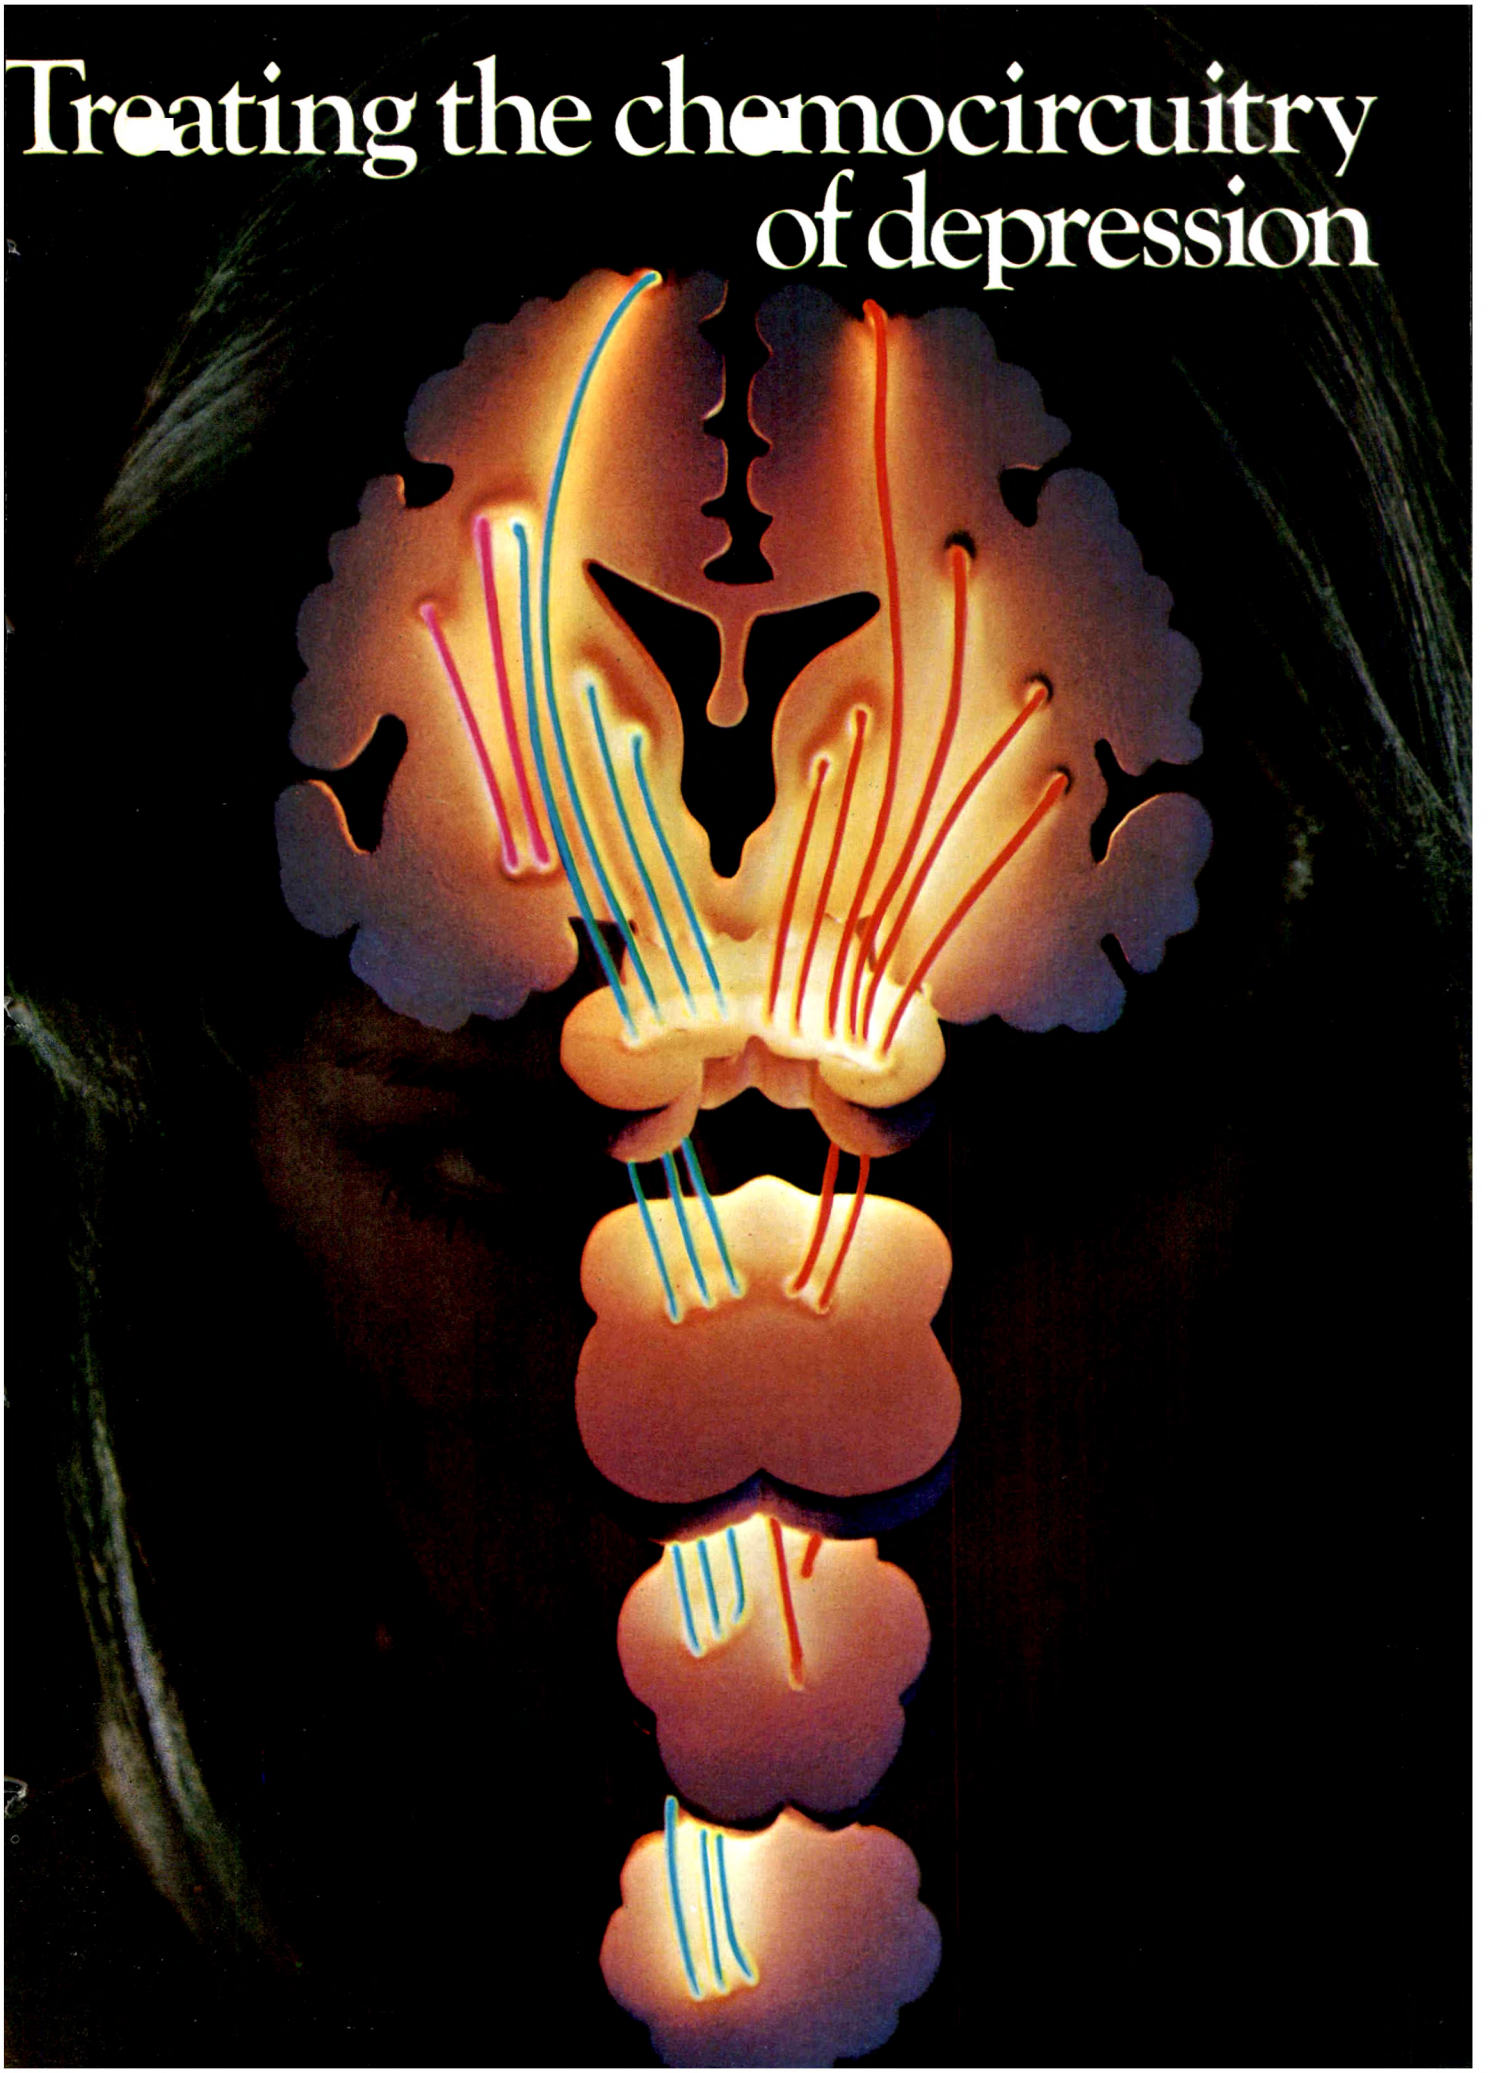
Gastrointestinal: nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of other tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.



How Supplied: Tablets, containing 5 mg and 10 mg protriptyline HCl each, in single-unit packages of 100 and bottles of 100 and 1000.

For more detailed information, consult your MSD representative or see full prescribing information.

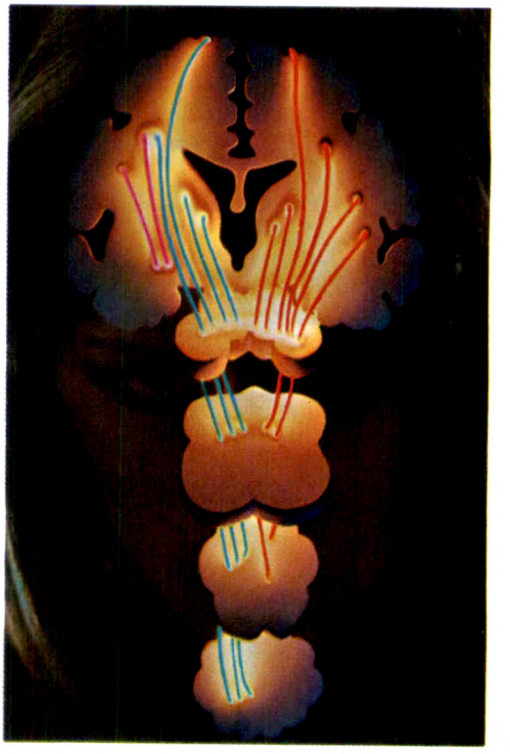
MERCK SHARP & DOHME



Treating the chemocircuitry of depression

Depression as an organic disease

At one time, depression was thought to be predominantly a behavioristic, nonmetabolic abnormality. But recent work on CNS catecholamine metabolism strongly suggests that biochemical factors are involved.

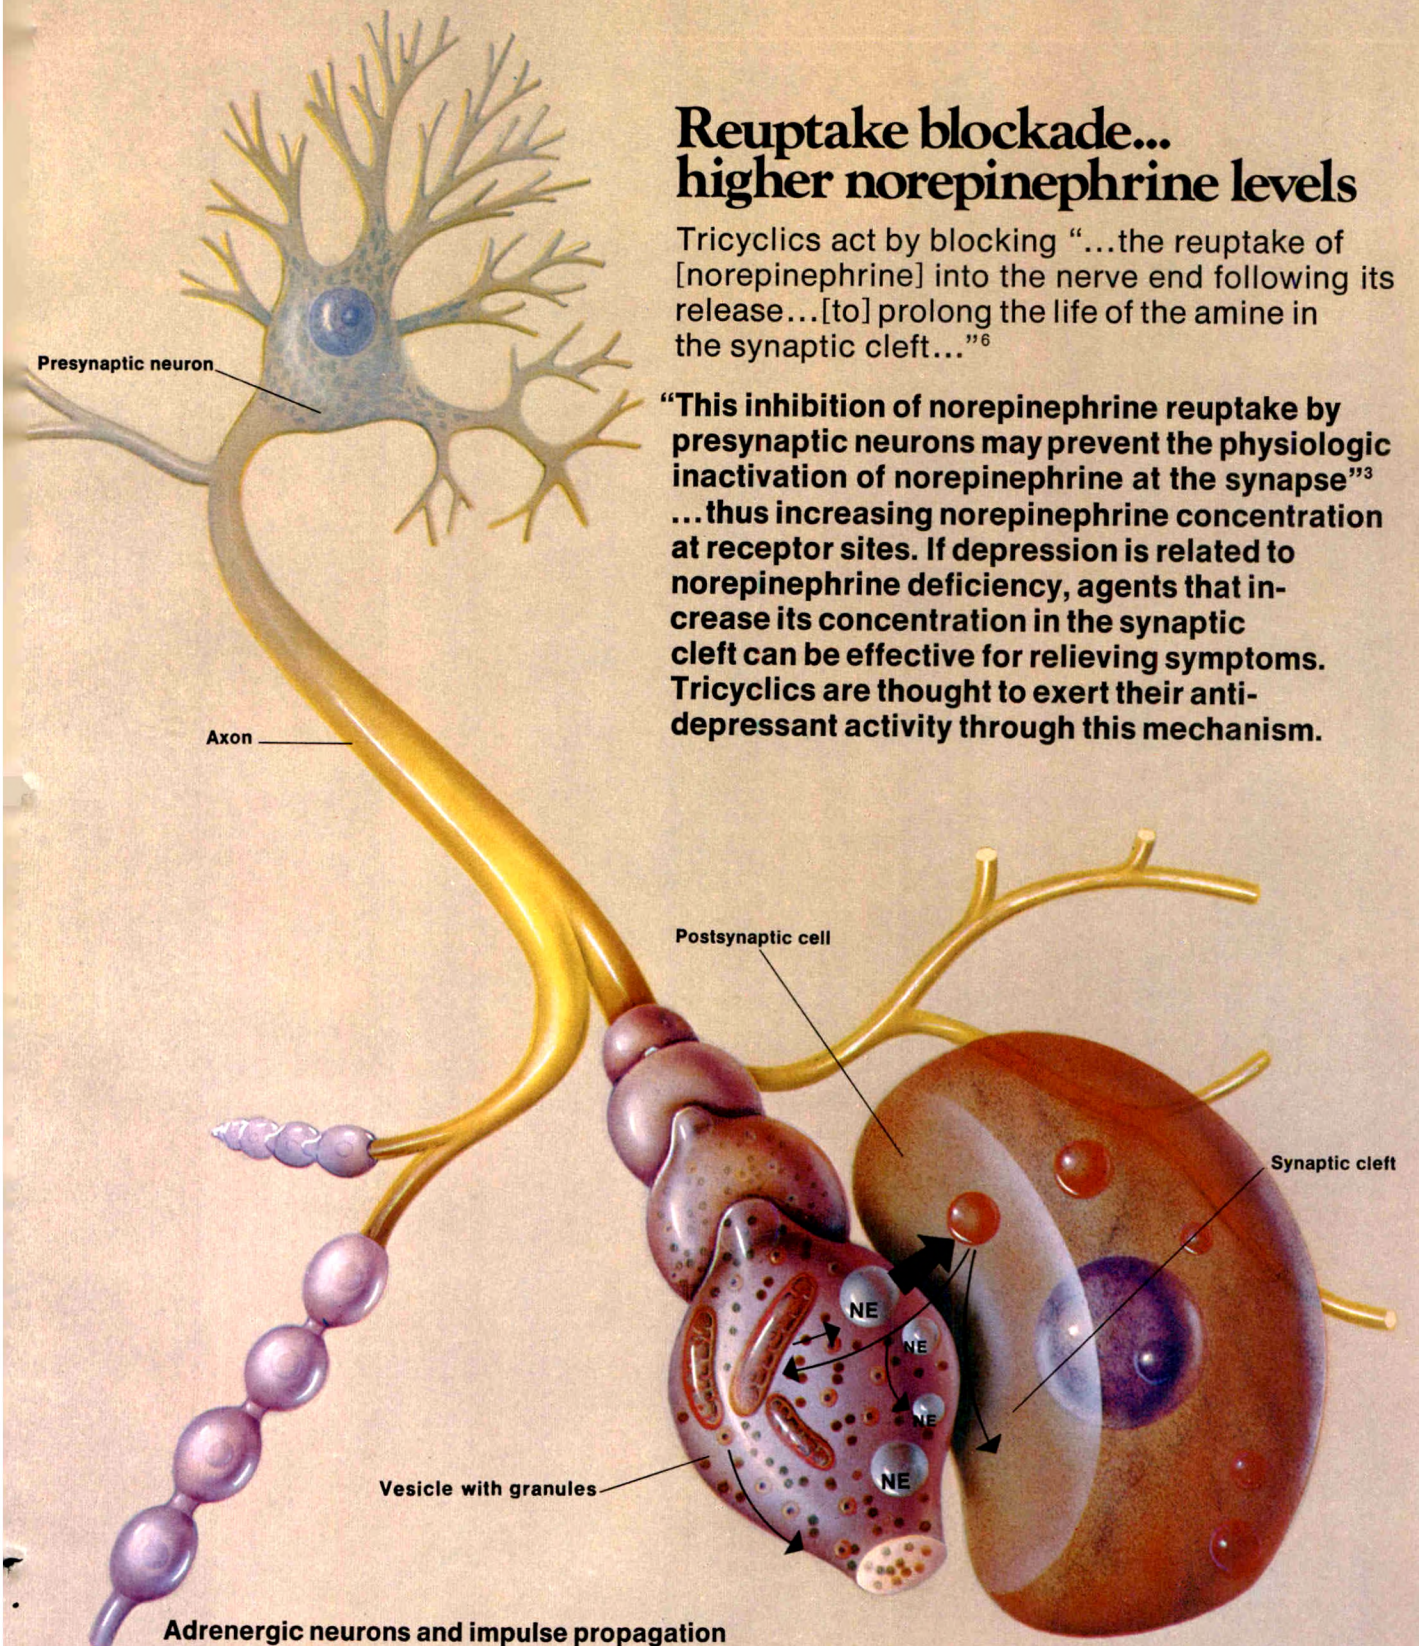
Theory of biogenic etiology

□ In individual nerve systems originating in the brainstem, impulses are relayed within each network by chemically distinct compounds—the biogenic amines.[1]

□ These compounds "... serve as neurotransmitters in brain sites that probably modulate feeling states, and other mental functions, that are disturbed in psychiatric disease."[2]

□ Amine systems involved in affective disorders[3] are:
norepinephrine (catecholamine)
dopamine (catecholamine)
serotonin (indoleamine)

There is a school of thought that associates catecholamines and affective disorders. According to this hypothesis, "... some, if not all, depressions are associated with an absolute or relative deficiency of catecholamines, particularly norepinephrine, at functionally important adrenergic receptor sites in the brain."[4]



"The possibility that depressed patients may have a functional deficiency of brain norepinephrine has gained considerable currency over the past decade."[5]

..and the efficacy of tricyclics

Reuptake blockade... higher norepinephrine levels

Tricyclics act by blocking "...the reuptake of [norepinephrine] into the nerve end following its release...[to] prolong the life of the amine in the synaptic cleft..."[6]

"This inhibition of norepinephrine reuptake by presynaptic neurons may prevent the physiologic inactivation of norepinephrine at the synapse"[3] ...thus increasing norepinephrine concentration at receptor sites. If depression is related to norepinephrine deficiency, agents that increase its concentration in the synaptic cleft can be effective for relieving symptoms. Tricyclics are thought to exert their antidepressant activity through this mechanism.

Adrenergic neurons and impulse propagation

□ Information coded as electric impulses arrives at synapse via axons of presynaptic neurons.

□ Impulses cause "release" of norepinephrine stored in vesicles adjacent to the presynaptic membrane.

□ Neurotransmitter migrates across the synaptic cleft and binds to receptors on postsynaptic cell membrane; it either triggers a new impulse or inhibits activity in the postsynaptic cell.

□ Because of the complex nature of brain activity, this action must be terminated rapidly and the cleft primarily cleared through reuptake of the transmitter into the presynaptic cell.

Tricyclics...the right choice in depression

Circuit functions and pharmacologic effects

Functioning of the biogenic amine systems, and how they are affected by therapeutic agents, underscore the value of tricyclics in depression.

The serotonin system: sedation/sleep

☐ Thought to regulate aspects of the sleep-wakefulness cycle and may be involved in REM sleep or dreaming.[2]
☐ Deficiency in turnover can produce symptomatology also present in depression.
☐ Some tricyclics, however, principally block the reuptake inactivation of serotonin.[6]
☐ **Activation of this system may therefore produce unwanted sedation.**

The dopamine system: motor activity

☐ Associated with normal posture and regulation of motor activity.
☐ Disturbed dopamine levels linked to symptoms of Parkinson's disease.
☐ "A possible relationship between decreased baseline... levels [of a dopamine metabolite] and decreases in motor activity in depressed patients has been suggested by some investigators..."[7]
☐ **Agents that influence this system can thus affect motor activity[6] and produce unwanted side effects.**

The norepinephrine system: mood

☐ Plays a major role in affective states.
☐ Deficiencies of norepinephrine linked to depression.
☐ Norepinephrine levels may be raised by psychomotor stimulants which cause release and block reuptake... by MAO inhibitors which block intraneuronal metabolism ...and by tricyclics through reuptake blockade.[1]
☐ Of these agents, the "most useful are the tricyclics."[6] They are preferred for their greater safety[8] and lower incidence of side effects.[9]
☐ **But tricyclics vary in their degree of interaction with other circuits—not only the catecholamines, but serotonin and acetylcholine as well.[10]**

Pertofrane®...the right choice in tricyclics
(desipramine hydrochloride NF)

Consider the chemistry

..qualitative and quantitative changes in the biochemical, pharmacological and clinical spectrum...[were produced by] the elimination of one of the N-methyl groups in the terminal amino group of imipramine to yield desipramine."[11]

..monomethylated forms of tricyclic antidepressants...are generally much more potent inhibitors of catecholamine re-uptake than dimethylated forms ..[whereas] dimethylated tricyclic antidepressants are more potent anticholinergics than the monomethylated forms."[12]

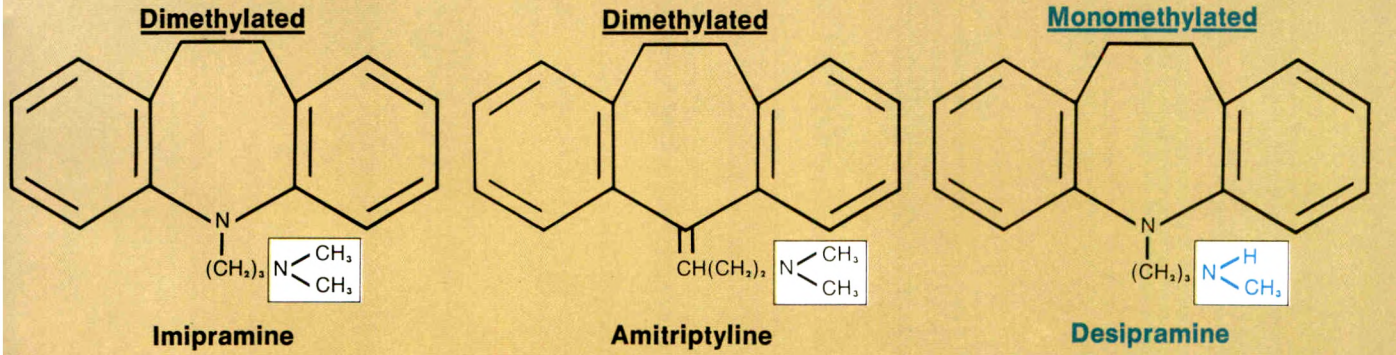
Dimethylated drugs are more potent serotonin blockers than monomethylated analogs. "Imipramine slows the turnover rate of [serotonin], an effect not shared by desipramine..."[13]

...compared to imipramine, [desipramine] is more 'procatechol' than 'proindole.' "[6]

...and the clinical implications

Rapid onset of action

Pertofrane has been found in some studies[14,16,19] to have a more rapid onset of action than imipramine. This relatively rapid onset of action may bring about prompt therapeutic response.



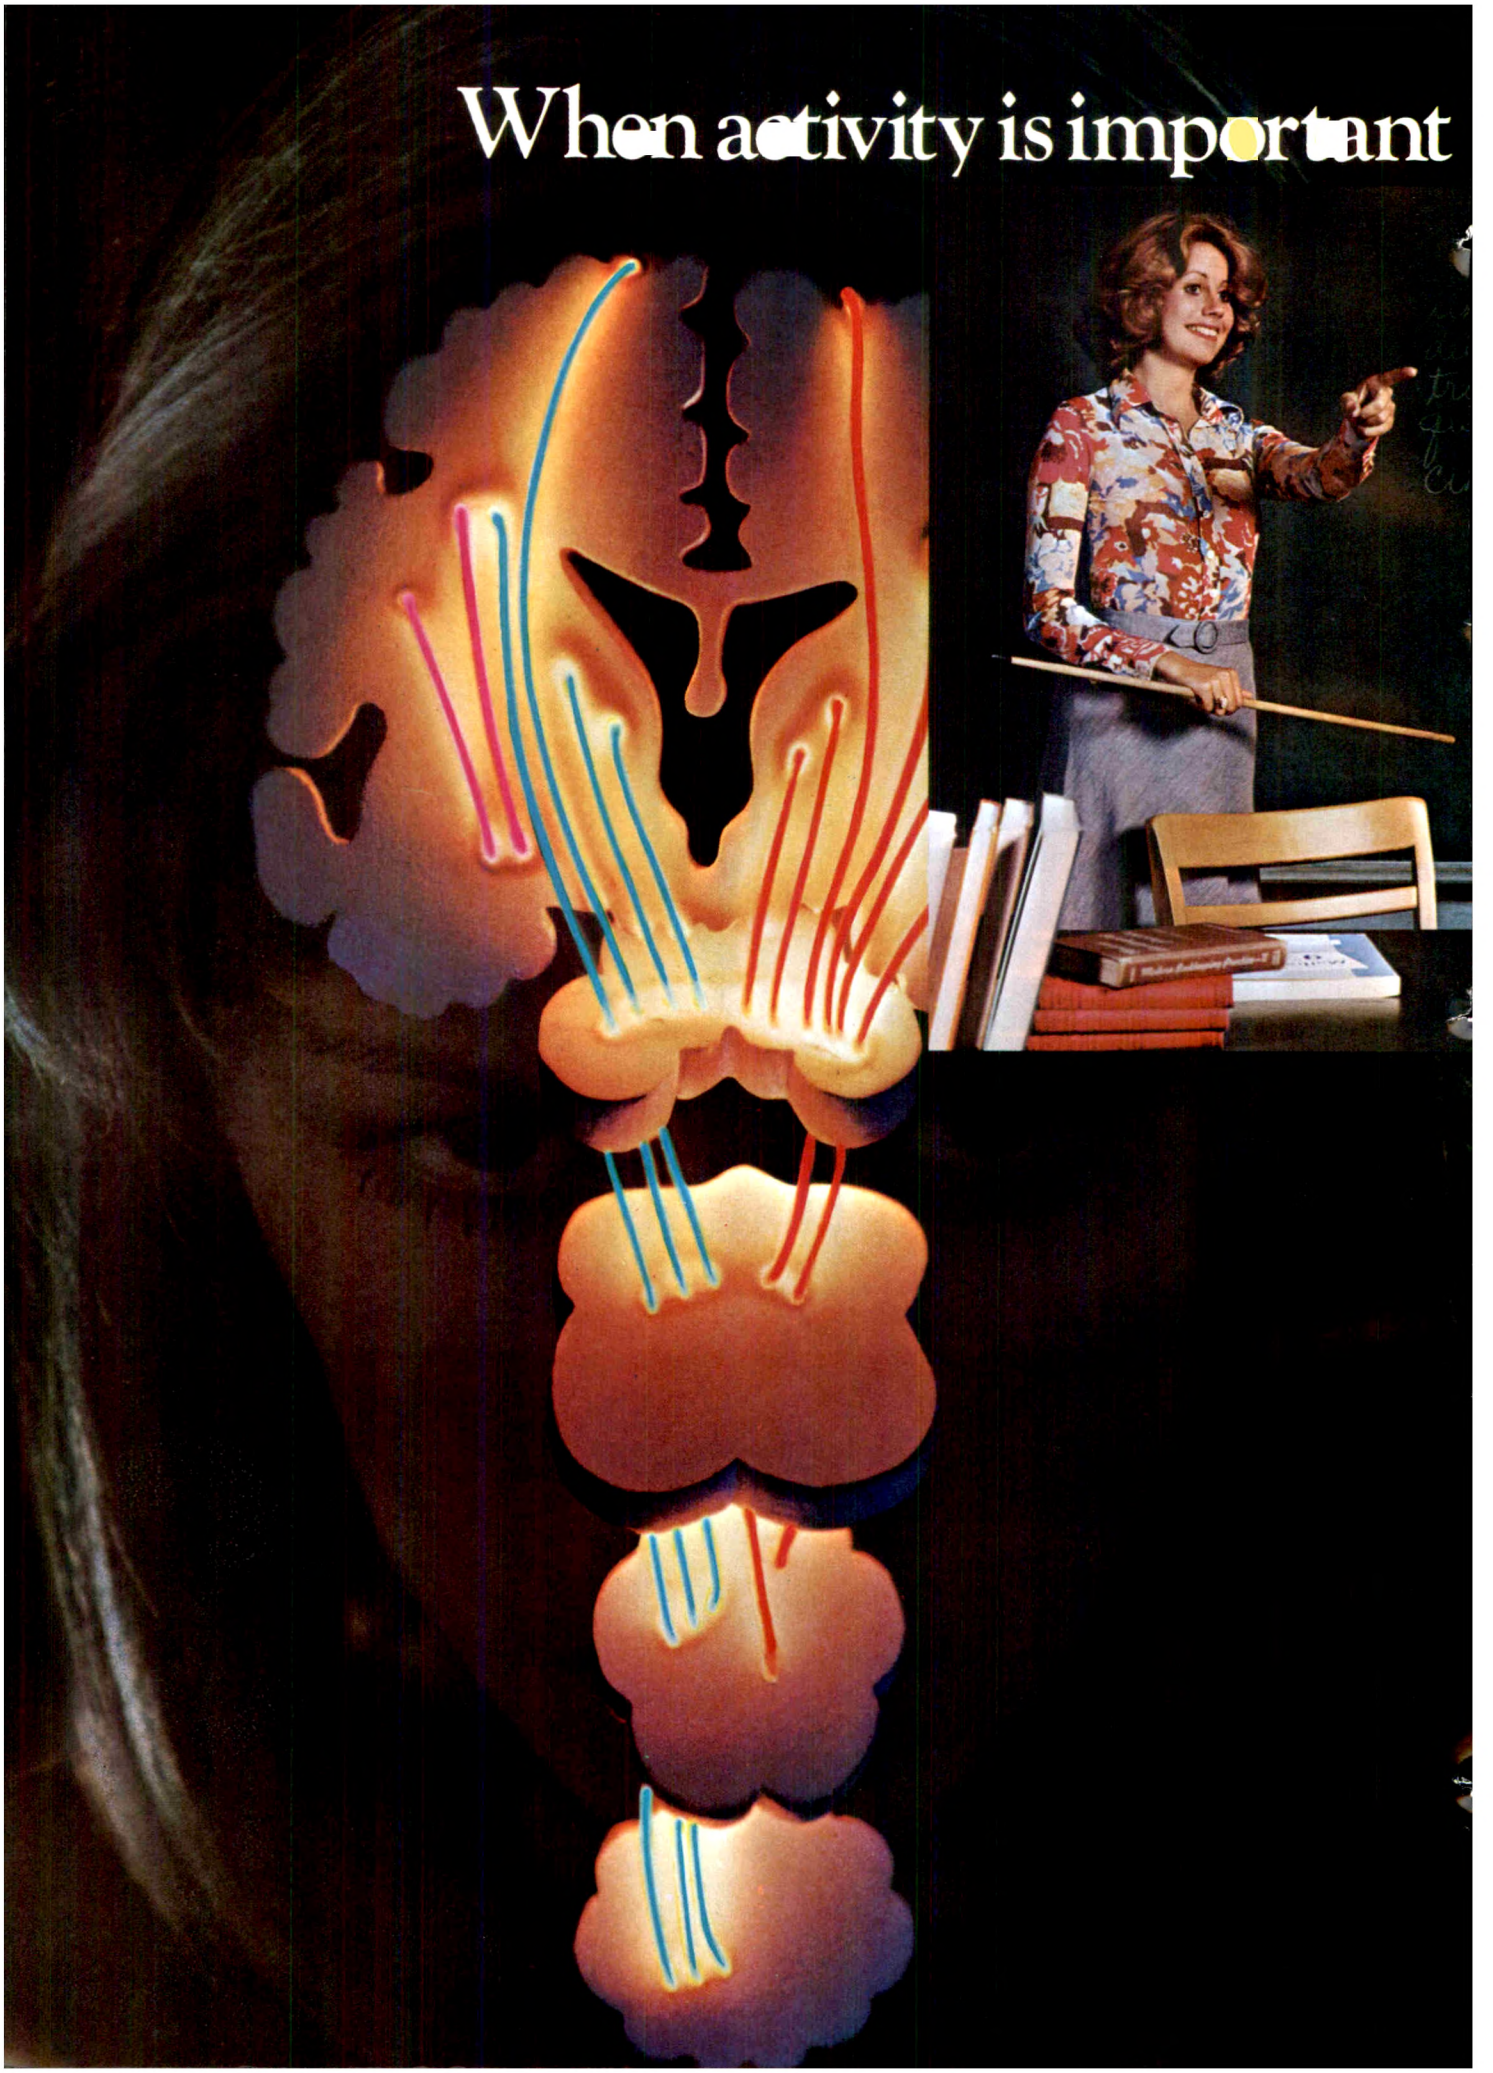
In a recent double-blind study comparing desipramine and amitriptyline, "the activity of desipramine becomes manifest rapidly and its beneficial effects further improve over time."[15]

Less sedative effect

Desipramine HCl shows good to excellent antidepressant effect yet is only mid-range in sedation.[6]

In a recent double-blind study comparing desipramine and amitriptyline in outpatients with depressive neurosis, while desipramine was equal or superior to amitriptyline in improving anxiety/depression and sleep disturbance factors, amitriptyline produced sedation in significantly more patients than did desipramine.[15]

UNIVERSITY OF MEDICINE & DENTISTRY LIBRARY



Imipramine **Amitriptyline** **Desipramine**

Selection of the right tricyclic for a particular patient can be based on structural activity relationships. And the profile of activity for a particular agent frequently depends on whether it is dimethylated or monomethylated.

Please see back cover for full prescribing information.

When activity is important

the neurochemistry's right for

Pertofrane®
(desipramine hydrochloride NF)

Proven clinical efficacy

☐ "...seems ideally suited to use in an active ambulatory patient population...[because of] its significant improvement of the depressed mood, work and activities..."[15]

☐ Effectiveness well documented in over a decade of clinical use.[9,16–18]

Prompt onset of action

☐ Relief may begin in 2 to 5 days—but full therapeutic effect is seldom seen before 2 weeks.

☐ Rapid onset of action[11,14,15,16,19] is particularly useful in patients who must continue to function actively during the course of therapy.

Mid-range sedation[6]

☐ Relieves associated mild anxiety/agitation, yet is only mid-range in sedative effect.

☐ "There is no problem of drowsiness"[16]—especially important when normal levels of daily activity must be maintained during treatment.

Compatible with tranquilizers/sedatives

☐ Where necessary, may be used with antianxiety or hypnotic agents.[16]

☐ Permits individualization of therapy when mild anxiety or agitation accompanies depression.

Provides dosage flexibility

☐ The therapeutic range is from 25 to 200 mg. daily. Patients may start at 25 mg. t.i.d. and dosage may be increased up to 200 mg./day according to patient needs.

Please see back cover for full prescribing information.

Pertofrane® (desipramine hydrochloride NF)

when activity is important

INDICATIONS: PERTOFRANE is indicated for the relief of mental depression (see Note before How Supplied section for additional information on depressive symptomatologies often responsive to this drug).

CONTRAINDICATIONS: The use of PERTOFRANE concomitantly or within two weeks of the administration of MAO inhibitors, is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse reactions can be serious, or even fatal. When it is desired to substitute PERTOFRANE in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation allows, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed.

The drug is contraindicated following recent myocardial infarction.

Patients with a known hypersensitivity to tricyclic antidepressants should not be given PERTOFRANE.

WARNINGS: As with other potent antidepressants, an activation of the psychosis may occasionally be observed in schizophrenic patients.

Due to the drug's atropine-like effects and sympathomimetic potentiation, PERTOFRANE should be used only with the greatest care in patients with narrow-angle glaucoma and with urethral or ureteral spasm.

Likewise, only when patient need outweighs the risk of serious adverse reactions should the drug be used in the presence of any of the following conditions: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (this agent has been shown to lower the seizure threshold).

In some instances, desipramine and the parent compound, imipramine, have been shown to block the pharmacologic action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents.

Hypertensive episodes have been observed during surgery in patients on desipramine hydrochloride therapy.

The concurrent use of other central nervous system drugs or alcohol may potentiate the adverse effects of desipramine hydrochloride. Since many such drugs may be used during surgery, it is recommended that desipramine hydrochloride be discontinued for as long as the clinical situation will allow prior to elective surgery.

Patients should be cautioned about the possibility of impaired ability to operate a motor vehicle or other dangerous machinery.

Usage in Pregnancy: Although teratogenic studies in mice, rats and rabbits have revealed no adverse effects, safe use of this drug in women who are or may become pregnant has not been definitely established. Therefore, PERTOFRANE should be withheld from these women unless the clinical situation warrants the potential risk.

In view of the lack of experience in children, the drug is not recommended for use in patients under twelve years of age.

Elderly and adolescent patients can usually be managed on lower dosage than that recommended for other patients and may not tolerate higher doses as well because of an increased incidence of adverse reactions.

PRECAUTIONS: It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until remission occurs. These patients require careful supervision and protective measures during therapy.

Anxiety and increased agitation have been reported, particularly where depression is not the primary disorder. A shift to hypomanic or manic excitement may occur during therapy. Such reactions may necessitate discontinuation of the drug.

Although the anticholinergic activity of the drug is weak, in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents), atropine-like effects may be more pronounced (e.g. paralytic ileus).

Caution should be observed in prescribing the drug in hyperthyroid patients and in those receiving thyroid medications. Transient cardiac arrhythmias have occurred in rare instances.

In all patients undergoing extended courses of therapy, periodic blood and liver studies for signs of toxicity should supplement careful clinical observations.

ADVERSE REACTIONS: PERTOFRANE (desipramine hydrochloride) is well tolerated by most patients and severe complications or adverse reactions are infrequent. Those most often reported cause little discomfort and seldom require discontinuation of the drug.

Nervous System: Dizziness, drowsiness, insomnia, headache and disturbed visual accommodation have been reported with the drug. In addition, tremor, unsteadiness, tinnitus and paresthesias have been reported. Occasionally, mild extrapyramidal activity, falling and neuromuscular incoordination have been seen. A confusional state (with such symptoms as hallucinations and disorientation) may be produced, particularly in older patients and at higher dosage, and may require discontinuation of the drug. Changes in EEG patterns have been observed. Epileptiform seizures may occur. A reduction in dosage may help control some of these adverse reactions.

Gastrointestinal Tract: Anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea have been reported in patients receiving PERTOFRANE.

Skin: Skin rashes (including photosensitization), perspiration and flushing sensations have been reported during therapy.

Liver: Transient jaundice, apparently of an obstructive nature, and liver damage have been observed in rare cases. Elevation in transaminase and changes in alkaline phosphatase have occurred and should indicate repeated liver-function profiles. If progressive elevation occurs, the drug should be discontinued.

Blood Elements: Bone-marrow depression, agranulocytosis, thrombocytopenia and purpura have been reported. If these occur, the drug should be discontinued. Transient eosinophilia has been observed in some instances.

Cardiovascular System: Orthostatic hypotension and tachycardia have been observed but seldom require discontinuation of treatment. Patients who require concomitant vasodilating therapy should be carefully supervised, particularly during the initial phas

Genitourinary System: Urinary frequency or retention and impotence have been repor

Endocrine System: Occasional hormonal effects, including gynecomastia, galactorrhe and breast enlargement have been reported with PERTOFRANE (desipramine hydrochloride). In addition, decreased libido and estrogenic effect have been noted. T exact relationship of these adverse effects to the administration of the drug has not be established.

Sensitivity: Urticaria and rare instances of drug fever and cross-sensitivity with imipramine have been observed.

DOSAGE AND ADMINISTRATION: *All Patients Except Geriatric and Adolescent:* Optimal results are obtained at a dosage of approximately 150 mg./day. PERTOFRAN may be administered as two 25 mg. capsules or one 50 mg. capsule t.i.d. (150 mg. da When necessary, dosage may be increased, after initiation of therapy, up to 200 mg. o in divided doses. Continued therapy at the optimal dosage level should be maintained during the active phase of the depression. It is recommended that a lower maintenanc dosage be continued for at least two months after a satisfactory response has been achieved.

In cases of relapse due to premature withdrawal of the drug, a prompt response may b obtained by immediate resumption of treatment.

Geriatric and Adolescent Patients: Elderly and adolescent patients can usually be managed on lower dosage and may not tolerate higher doses as well as other patients Therapy in these age groups may be initiated with 25 to 50 mg. daily. Dosage may be increased according to response and tolerance, but it is generally unnecessary to exce 100 mg. daily in these patients. It is recommended that a lower maintenance dosage b continued for at least two months after a satisfactory response has been achieved.

Mild anxiety and agitation which often accompany cases of depression usually remit as the depression responds to PERTOFRANE. Occasionally, however, when anxiety an agitation are more serious, the adjunctive use of a sedative or tranquilizing agent may b indicated.

NOTE: Depressions which are most responsive to PERTOFRANE may be described i terms of "target symptoms." These include: despondency, sadness and depressed mood; fatigue; lack of interest and emotional response; helplessness, hopelessness, pessimism and despair; feelings of incapacity and inferiority; psychomotor retardation and inhibition; delusions of guilt and unworthiness; psychosomatic complaints; insomni anorexia and weight loss; depression-related anxiety and agitation; suicidal drive.

It should be borne in mind that these "target symptoms" of depression assume their proper significance only after careful history, physical and mental evaluations and other investigative procedures have confirmed a diagnosis of one of the several types of depression.

HOW SUPPLIED: 25 mg. Capsules (pink), bottles of 100 and 1000 (NSN 6505-00-913 0382A). Also, 50 mg. Capsules (maroon and pink), bottles of 100 and 1000; single-dose blister packs, boxes of 500.

USV PHARMACEUTICALS

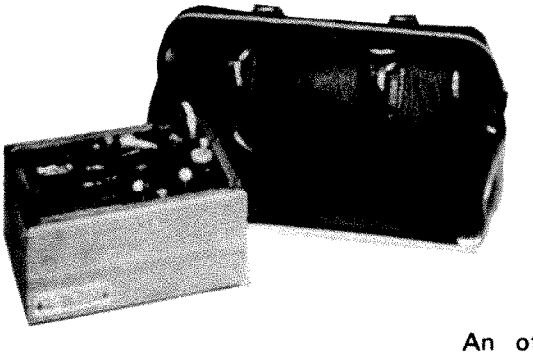
USV Pharmaceutical Mfg. Corp.
Manati, P.R. 00701

MORE THAN 30 YEARS...

have proven the dependability and effectiveness of REITER ELECTROSTIMULATORS in psychiatry! Research and constant improvements to meet the standards of improved techniques have kept Reiter instruments

THE WORLD'S MOST ACCEPTED ELECTROSTIMULATORS

The Two Popular Models— **PORTABLE FOR OFFICE AND CLINIC**



The Reiter MODEL SOS—THE ONE INSTRUMENT FOR ALL ESTABLISHED TECHNIQUES, provides the fullest range of safest therapies. For painless, gentle stimulation of the conscious patient to relieve anxiety, depression, etc. Maximum safety, no additives—patient conscious and cooperating with therapy.

The SOS has also been used universally for Convulsive Therapy, Non-Convulsive Therapies, Electro-Sleep Therapy, Focal Treatment, Mono-Polar Treatment, Barbiturate Coma (and other respiratory problems), Mild Sedac, Deep Sedac Therapy, Pre-Convulsive Sedac, Post-Convulsive Sedac, Neurological Conditions, and Measurement Procedures.

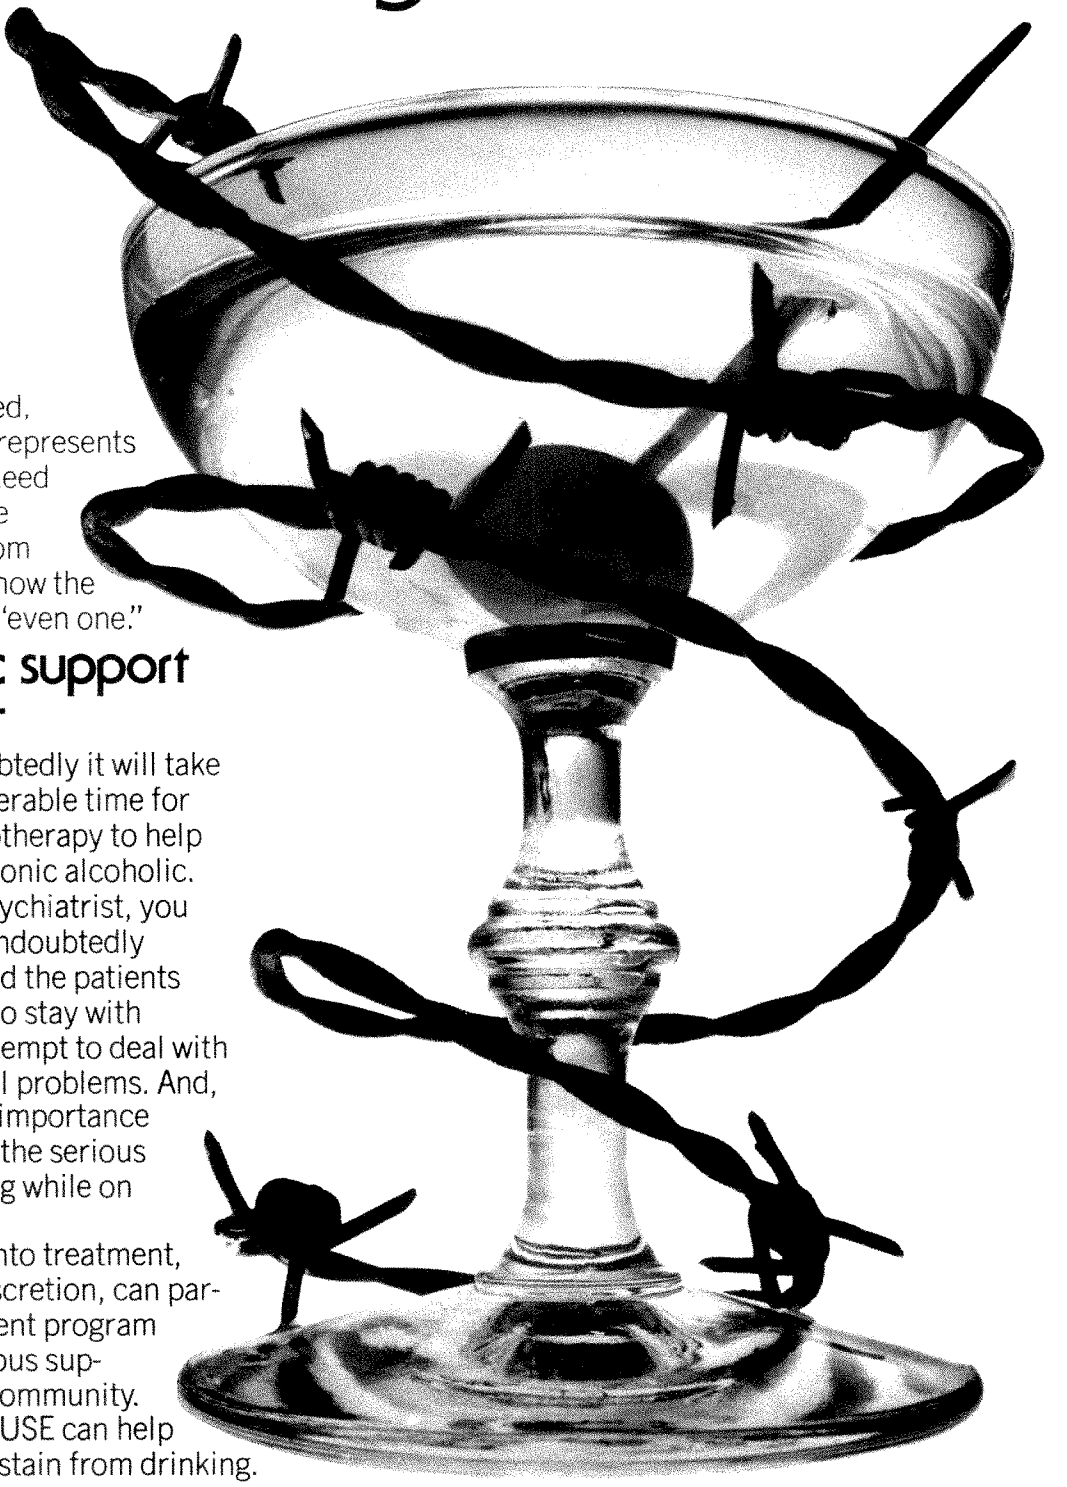
Available with this redesigned model, on request, the following special-purpose electrodes —a Multi-Polar "Collar" type for Sleep Therapy, a "Horseshoe" assembly for quicker, surer application with one hand at last moment before ECT treatment, and a "Unilateral" type assembly.

Also built-in on request, an **automatic switch** for quicker build up to therapeutic ranges of Sedac.

SPECIAL MODEL SOS available without unidirectional convulsive current.

The Reiter Compact MOL-AC II—The smallest, lightest, least expensive and most reliable, clinically proven A.C. shock therapy instrument. Less confusion than from similar A.C. equipment. Now available with redesigned, improved panel. This compact instrument is only 3 x 5 inches, weighs but 3 lbs., yet provides full positive control of glisando effect over entire voltage range, as well as a positive manual control of time. There are NO complicated settings of dials, NO waiting for resetting of time devices, no warm-up delays.

An officially approved, extremely durable instrument which has earned world-wide professional acceptance, the MOL-AC II is economically priced with a fine, genuine leather physician's bag included.



Other Models Still Available: The CW47, original therapeutic cerebral stimulator with only 3 of the 9 treatment current selections available on Model SOS.

ANTABUSE: "Social security" for the alcoholic who wants to stop drinking...

The temptation is resisted, ANTABUSE (disulfiram) represents the security alcoholics need in any situation. They are better able to abstain from drinking because they know the consequences of taking "even one."

until psychiatric support can do the rest

Undoubtedly it will take considerable time for psychotherapy to help the chronic alcoholic. As a psychiatrist, you have undoubtedly selected the patients who are best motivated to stay with ANTABUSE while you attempt to deal with the underlying emotional problems. And, of course, you know the importance of reminding patients of the serious consequences of drinking while on ANTABUSE.

Once sober, and well into treatment, the alcoholic, at your discretion, can participate in a total treatment program which makes use of various supportive resources in the community. In the meantime, ANTABUSE can help the chronic alcoholic abstain from drinking.

BRIEF SUMMARY
(For full prescribing information, see package circular.)

ANTABUSE® (disulfiram) in Alcoholism

INDICATION: ANTABUSE is an aid in the management of selected chronic alcoholic patients who want to remain in a state of enforced sobriety so that supportive and psychotherapeutic treatment may be applied to best advantage. (Used alone, without proper motivation and without supportive therapy, ANTABUSE is not a cure for alcoholism, and it is unlikely that it will have more than a brief effect on the drinking pattern of the chronic alcoholic.)

CONTRAINDICATIONS: Patients who are receiving or have recently received metronidazole, paraldehyde, alcohol, or alcohol-containing preparations, e.g. cough syrups, tonics, and the like, should not be given ANTABUSE.

ANTABUSE is contraindicated in the presence of severe myocardial disease or coronary occlusion, psychoses, or hypersensitivity.

WARNINGS: ANTABUSE should never be administered to a patient when he is in a state of alcohol intoxication or without his full knowledge.

The physician should instruct relatives accordingly.

The patient must be fully informed of the ANTABUSE-alcohol reaction. He must be strongly cautioned against surreptitious drinking while taking the drug, and he must be fully aware of possible consequences. He should be warned to avoid alcohol in disguised form, *i.e.* in sauces, vinegars, cough mixtures, and even aftershave lotions and back rubs. He should also be warned that reactions may occur with alcohol up to 14 days after ingesting ANTABUSE.

THE ANTABUSE-ALCOHOL REACTION: ANTABUSE plus alcohol, even small amounts, produces flushing, throbbing in head and neck, throbbing headache, respiratory difficulty, nausea, copious vomiting, sweating, thirst, chest pain, palpitation, dyspnea, hyperventilation, tachycardia, hypotension, syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion. In severe reactions there may be respiratory depression, cardiovascular collapse, arrhythmias, myocardial infarction, acute congestive heart failure, unconsciousness, convulsions, and death.

The intensity of the reaction varies with each individual, but is generally proportional to the amounts of ANTABUSE (disulfiram) and alcohol ingested. Mild reactions may occur in the sensitive individual when the blood alcohol concentration is increased to as little as 5 to 10 mg. per 100 cc. Symptoms are fully developed at 50 mg. per 100 cc., and unconsciousness usually results when the blood alcohol level reaches 125 to 150 mg.

The duration of the reaction varies from 30 to 60 minutes to several hours in the more severe cases, or as long as there is alcohol in the blood.

DRUG INTERACTIONS: Disulfiram appears to decrease the rate at which certain drugs are metabolized and so may increase the blood levels and the possibility of clinical toxicity of drugs given concomitantly.

Disulfiram should be used with caution in those patients receiving diphenylhydantoin and its congeners, since toxic levels of these antiepileptic agents have been reported during concomitant disulfiram therapy.

It may be necessary to adjust the dosage of oral anticoagulants upon beginning or stopping disulfiram, since disulfiram may prolong prothrombin time.

Patients taking isoniazid when disulfiram is given should be observed for the appearance of unsteady gait or marked changes in mental status and the disulfiram discontinued if such signs appear.

CONCOMITANT CONDITIONS: Because of the possibility of an accidental ANTABUSE-alcohol reaction, ANTABUSE (disulfiram) should be used with extreme caution in patients with any of the following conditions: diabetes mellitus, hypothyroidism, epilepsy, cerebral damage, chronic and acute nephritis, hepatic cirrhosis or insufficiency.

USAGE IN PREGNANCY: The safe use of this drug in pregnancy has not been established. Therefore, ANTABUSE (disulfiram) should be used during pregnancy only when, in the judgment of the physician, the probable benefits outweigh the possible risks.

PRECAUTIONS: It is suggested that every patient under treatment carry an Identification Card, stating that he is receiving ANTABUSE and describing the symptoms most likely to occur as a result of the ANTABUSE-alcohol reaction. In addition, this card should indicate the physician or institution to be contacted in emergency. (Cards may be obtained from Ayerst Laboratories upon request.)

Alcoholism may accompany or be followed by dependence on narcotics or sedatives. Barbiturates have been administered concurrently with ANTABUSE (disulfiram) without untoward effects, but the possibility of initiating a new abuse should be considered.

Base line and follow-up transaminase tests (10-14 days) are suggested to detect any hepatic dysfunction that may result with ANTABUSE therapy. In addition, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

ADVERSE REACTIONS: (See Contraindications, Warnings, and Precautions.)

Occasional skin eruptions are, as a rule, readily controlled by concomitant administration of an antihistaminic drug.

In a small number of patients, a transient mild drowsiness, fatigability, impotence, headache, acneform eruptions, allergic dermatitis, or a metallic or garlic-like aftertaste may be experienced during the first two weeks of therapy. These complaints usually disappear spontaneously with the continuation of therapy or with reduced dosage.

Psychotic reactions have been noted, attributable in most cases to high dosage, combined toxicity (with metronidazole or isoniazid), or to the unmasking of underlying psychoses in patients stressed by the withdrawal of alcohol.

There have been reports of polyneuritis and peripheral neuritis, and rare instances of optic neuritis. One case of cholestatic hepatitis has been reported, but its relationship to ANTABUSE has not been unequivocally established.

DOSAGE AND ADMINISTRATION: ANTABUSE (disulfiram) should never be administered until the patient has abstained from alcohol for at least 12 hours.

INITIAL DOSAGE SCHEDULE: In the first phase of treatment, a maximum of 500 mg. daily is given in a single dose for one to two weeks. Although usually taken in the morning, ANTABUSE may be taken on retiring by patients who experience a sedative effect. Alternatively, to minimize, or eliminate, the sedative effect, dosage may be adjusted downward.

MAINTENANCE REGIMEN: The average maintenance dose is 250 mg. daily (range, 125 to 500 mg.); it should not exceed 500 mg. daily.

NOTE: Occasional patients, while seemingly on adequate maintenance doses of ANTABUSE (disulfiram), report that they are able to drink alcoholic beverages with impunity and without any symptomatology. All appearances to the contrary, such patients must be presumed to be disposing of their tablets in some manner without actually taking them. Until such patients have been observed reliably taking their daily ANTABUSE tablets (preferably crushed and well mixed with liquid), it cannot be concluded that ANTABUSE is ineffective.

DURATION OF THERAPY: The daily, uninterrupted administration of ANTABUSE must be continued until the patient is fully recovered socially and a basis for permanent self-control is established. Depending on the individual patient, maintenance therapy may be required for months or even years.

TRIAL WITH ALCOHOL: During early experience with ANTABUSE, it was thought advisable for each patient to have at least one supervised alcohol-drug reaction. More recently, the test reaction has been largely abandoned. Furthermore, such a test reaction should never be administered to a patient over 50 years of age. A clear, detailed, and convincing description of the reaction is felt to be sufficient in most cases.

However, where a test reaction is deemed necessary, the suggested procedure is as follows:

After the first one to two weeks' therapy with 500 mg. daily, a drink of 15 cc. (½ oz.) of 100 proof whiskey or equivalent is taken slowly. This test dose of alcoholic beverage may be repeated once only so that the total dose does not exceed 30 cc. (1 oz.) of whiskey. Once a reaction develops, no more alcohol should be consumed. Such tests should be carried out only when the patient is hospitalized, or comparable supervision and facilities, including oxygen, are available.

MANAGEMENT OF ANTABUSE (DISULFIRAM)-ALCOHOL REACTION: In severe reactions, whether caused by an excessive test dose or by the patient's unsupervised ingestion of alcohol, supportive measures to restore blood pressure and treat shock should be instituted. Other recommendations include: oxygen, carbogen (95 per cent oxygen and 5 per cent carbon dioxide), vitamin C intravenously in massive doses (1 Gm.), and ephedrine sulfate. Antihistamines have also been used intravenously. Potassium levels should be monitored particularly in patients on digitalis since hypokalemia has been reported.

HOW SUPPLIED: No. 809—Each tablet (scored) contains 250 mg. disulfiram, in bottles of 100. No. 810—Each tablet (scored) contains 500 mg. disulfiram, in bottles of 50 and 1,000.

ANTABUSE®

BRAND OF DISULFIRAM

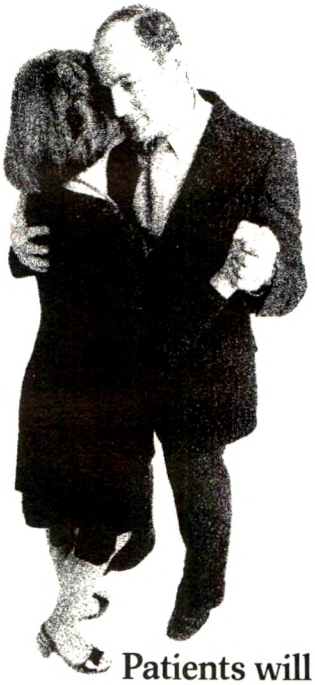
ROCHE

Introducing

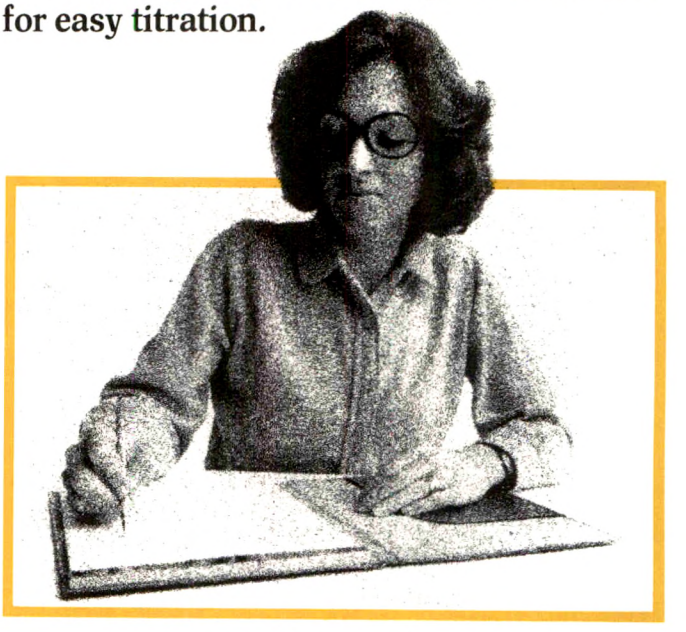
The unforgettable antidepressant

Endep™ 75 mg

amitriptyline HCl/Roche



Here's what makes it unforgettable



Patients are more likely to remember the single bedtime dosage of Endep (amitriptyline HCl).

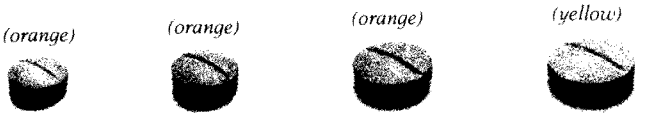
You'll remember 1 or 2 tablets *h.s.*, because fewer forgotten doses produce a more consistent clinical effect, and because it is the only tricyclic antidepressant scored for easy titration.

Patients will also remember family/interpersonal relationships that they have forgotten or neglected.

In three or four weeks patients will usually remember how well they used to feel.

Endep™ 75 mg

amitriptyline HCl/Roche



The antidepressant you can prescribe at night to work all day

Before prescribing, please consult complete product information, a summary of which appears on the following page.

Introducing Endep™

amitriptyline HCl/Roche

The antidepressant you can prescribe at night to work all day

10-mg scored tablets | **25-mg** scored tablets | **50-mg** scored tablets | **75-mg** scored tablets

■ Endep (amitriptyline HCl), in responsive patients, lifts mood and relieves symptoms such as anorexia, loss of interest, inability to concentrate, decreased libido or GI disturbances, often within three or four weeks after starting therapy.

■ Endep usually relieves accompanying sleep disturbances, particularly early in the treatment regimen.

■ All four dosage strengths are scored for greater flexibility and convenience in titration.

■ The 75-mg *h.s.* dose minimizes skipped doses, maximizes patient acceptance and compliance.

■ Specifying Endep/Roche assures quality plus potential economy.

Important Considerations

Should not be given concomitantly with an MAO inhibitor.

Not recommended for use during the acute recovery phase following myocardial infarction.

Contraindicated in patients with hypersensitivity to amitriptyline.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: To relieve symptoms of depression (notably endogenous depression) and depression accompanied by anxiety.

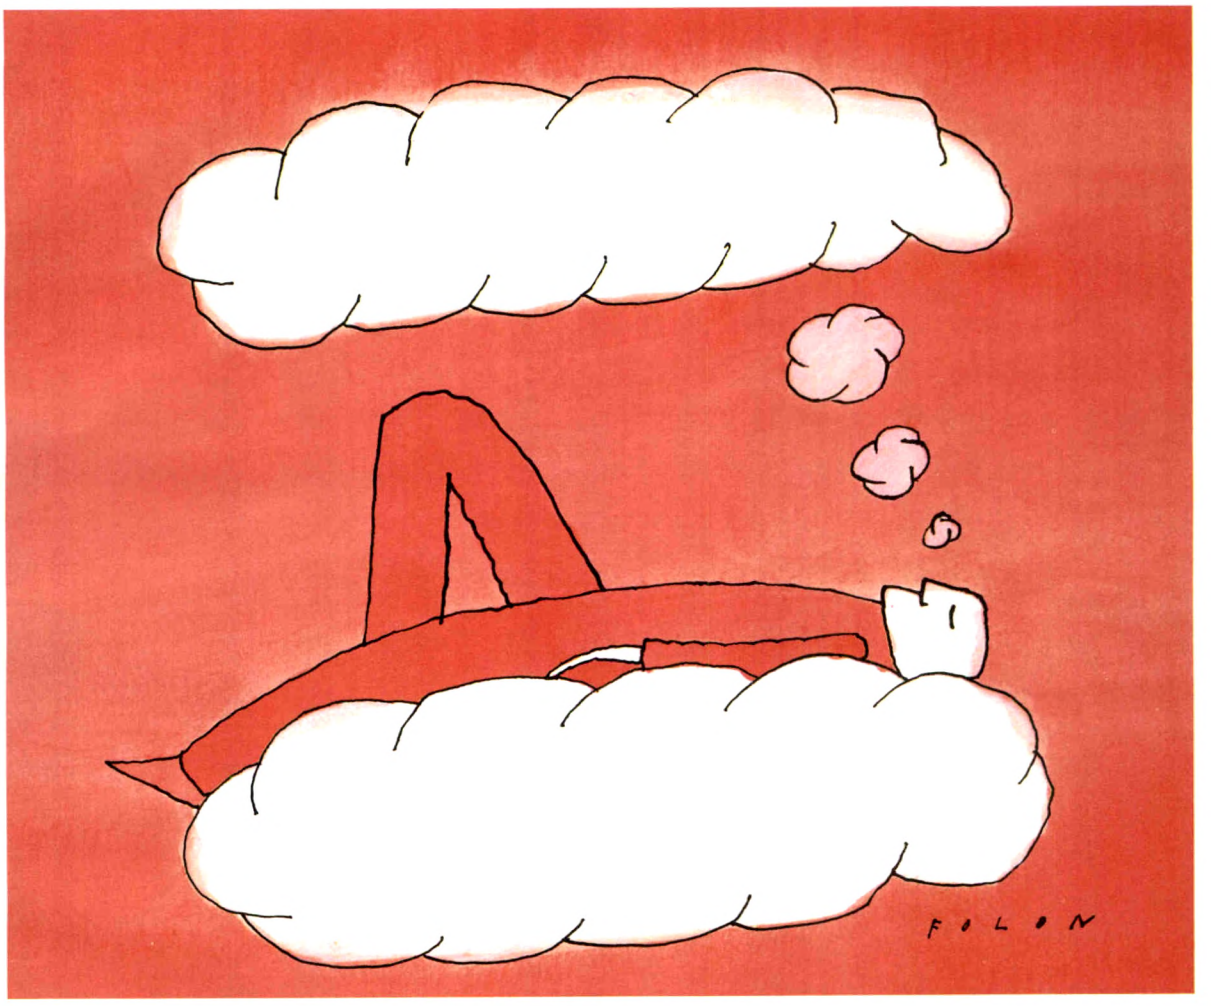
Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh potential benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Dosage: Initiate at low levels; increase gradually, watching for signs of intolerance. As long as 30 days may elapse before adequate antidepressant effect develops; sedative effect may be noted earlier. *Initial Adult Dosage:* Outpatients – 25 mg t.i.d.; may be increased to 150 mg/day. Add increased drug to afternoon and/or bedtime doses. Alternate – 50 to 100 mg h.s., gradually increasing h.s. dose up to 150 mg/day. Hospitalized Patients – Up to 100 mg/day; increase gradually to 200 mg if necessary. A few patients may require 300 mg/day. *Adolescent and Elderly Patients:* In general, 10 mg t.i.d. with 20 mg h.s. may be satisfactory for those who do not tolerate higher doses. *Maintenance Dosage:* With symptomatic improvement, reduce dosage to lowest amount that gives relief, usually 25 mg b.i.d. to q.i.d., or 10 mg q.i.d. Continue maintenance therapy 3 months or longer to avoid relapse.



Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. IV administration of 1 to 3 mg physostigmine salicylate reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestations and treatment.

Supplied: 10-mg, 25-mg, 50-mg and 75-mg scored tablets – bottles of 100 and 500; Prescription Paks of 60 (10 mg, 25 mg and 50 mg) or 30 (75 mg), available singly and in trays of 10.

Prize competition

announced by the

Anna Monika Foundation

for the investigation of the physical substrate and functional disturbances of endogenous depressions by approval of the Minister of the Interior of Nordrhein-Westfalen, Düsseldorf, on 9th June, 1965.

The Foundation announces the following prizes:

FIRST PRIZE	**10.000, - US Dollars**
SECOND PRIZE	**5.000, - US Dollars**
THIRD PRIZE	**2.500, - US Dollars**

preferably for studies of biochemical, histological, neurophysiological, neuropathological, psychopharmacological, psychiatric or psychosomatic nature. The studies should be carried out in close co-operation with a psychiatric clinic, a university institute or an equivalent scientific institution. So far as possible, *the papers should give information about recent advances* in knowledge that would be helpful in promoting treatment and would open up new paths of progress. The papers may be written in German, French or English and should be submitted to the chairman of the committee, Professor Dr. Kielholz, Basle, Switzerland. Besides hitherto unpublished studies, papers published in the past two years in a German or international professional journal may also be submitted. *Deadline for submission to the Committee is 30th September, 1976.* To help the Committee to come to a speedy decision it is requested that at least four copies including an abstract covering the content of all papers should be submitted. Prizes will be awarded on the 30th June, 1977. If, in the opinion of the Committee, no papers of sufficient merit are submitted, it reserves the right to make no award. Prizes and their amount will be awarded according to the merits of the study in question. Subject to the Committee's decision, each prize can be divided between two papers.

The Committee of Judges Includes:

Chairman: Professor Dr. P. Kielholz, Director of the Psychiatric Clinic of the University of Basle, CH-4056 Basle, Switzerland, Wilhelm-Klein-Strasse 27.

Professor Dr. Karl Bernhard, Institute for Physiological Chemistry, Basle, Switzerland

Professor Dr. Otto Creutzfeldt, Director of the Max-Planck-Institute of Biophysical Chemistry, Göttingen, Germany

Professor Dr. H.J. Dengler, Director of the Medical Clinic of University Bonn, Germany

Professor Dr. Fritz A. Freyhan, M.D., F.A.P.A. Washington, D.C. 20009, USA

Professor Dr. K. Heinrich, Director of the Psychiatric Clinic of the University of Düsseldorf, Germany

Professor Dr. H. Hippius, Director of the Psychiatric Clinic and Out-patient Clinic Munich, Germany

Professor Dr. Horst Jatzkewitz, Director of the Max-Planck-Institute for Psychiatry, Neurochemical Department, Munich, Germany

Professor Dr. D. Palm, Director of the Pharmalogical Institute of the University of Frankfurt/ Main, Germany

Professor Pierre Pichot, Head of Medical Psychology, Centre Psychiatrique Sainte-Anne, Paris, France

Professor Dr. Wilhelm Stoffel, Director of the Institute of Physiological Chemistry, University of Cologne, Germany.

Director of the Foundation: PETER REHME, D-4600 DORTMUND, TÖLLNERSTR. 9/11

The familiar refrain of depression: morning fatigue... sadness... anorexia... insomnia

Now, Merrell offers Norpramin (desipramine hydrochloride tablets N.F.) to effectively relieve these common manifestations of depression.

Norpramin also provides additional benefits in treatment of your patients.

- ☐ effectively relieves physical, psychological and emotional symptoms of depression
- ☐ minimal daytime sedation — important for patients who must be alert to perform daytime activities
- ☐ relief that may begin in 2 to 5 days — but full therapeutic effect is seldom seen before 2 weeks
- ☐ side effects rarely require discontinuation of therapy
- ☐ increases interpersonal responsiveness
- ☐ can help facilitate psychotherapy

Prescribe Norpramin to change the familiar refrain of depression in your practice.

Norpramin®
(desipramine hydrochloride tablets N.F.)

Brief Summary

Indications: Norpramin (desipramine hydrochloride tablets N.F.) is indicated for the relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Desipramine hydrochloride should not be given within two weeks of treatment with a monoamine oxidase inhibitor. Contraindications include the acute recovery period following myocardial infarction and hypersensitivity to the drug. Cross sensitivity with other dibenzazepines is a possibility.

Warnings: 1. Extreme caution should be used in patients: (a) with cardiovascular disease. (b) with a history of urinary retention or glaucoma. (c) with thyroid disease or those on thyroid medication. (d) with a history of seizure disorder. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. *Use in Pregnancy:* Safe use during pregnancy and lactation has not been established. 4. *Use in Children:* Norpramin is not recommended for use in children. 5. This drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. Therefore, the patient should be cautioned accordingly.

Precautions: This drug should be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with drugs of this class. If possible, dispense in child-resistant containers. It should be kept out of reach of children. Reduce dosage, or alter treatment, if serious adverse effects occur. Norpramin therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates and may cause exacerbation of psychosis in schizophrenic patients. Use cautiously with anticholinergic or sympathomimetic drugs. Response to alcoholic beverages may be exaggerated. In the concurrent administration of ECT and antidepressant drugs one should consider the possibility of increased risk relative to benefits. Discontinue as soon as possible prior to elective surgery because of possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients on desipramine hydrochloride. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy: the drug should be discontinued if there is neutropenia.

Adverse Reactions: *Cardiovascular:* hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke. *Psychiatric:* confusional states (especially in the elderly), hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis. *Neurological:* numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus. *Anticholinergic:* dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, hypotonic bladder. *Allergic:* skin rash, petechiae, urticaria, itching, photosensitization, edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs. *Hematologic:* bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue. *Endocrine:* gynecomastia, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels. *Other:* jaundice (simulating obstructive), altered liver function; weight gain or loss, perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia. *Withdrawal Symptoms:* Though not indicative of addiction, abrupt cessation after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: *The usual adult dose:* 50 mg. three times daily; increase if necessary after 7 to 10 days to maximum of 200 mg. daily. Dosages above 200 mg. per day are not recommended. *Maintenance:* At a lower dose adequate to maintain remission. *Adolescent and geriatric patient dose:* 25 to 50 mg. daily; increase to 100 mg. daily if necessary.

Overdosage: There is no specific antidote for desipramine, nor are there specific phenomena of diagnostic value characterizing poisoning by the drug. The principles of management of coma and shock by means of the mechanical respirator, cardiac pacemaker, monitoring of central venous pressure and regulation of fluid and acid-base balance are well known in most medical centers. If heart failure is imminent, digitalize promptly.

The TRIAVIL® Potential in the management of moderate to severe anxiety with depression

When time and talk are not enough...
The therapist is the primary catalyst for change in the psychotherapeutic relationship. However, when patients suffer from moderate to severe anxiety with depression, there are situations when TRIAVIL can often be a useful adjunct.

...TRIAVIL may help
There are three important benefits you may expect when TRIAVIL is part of the treatment program: (1) When symptoms of moderate to severe anxiety or agitation with depression are relieved, the patient may become more accessible and cooperative. (2) As somatic manifestations are controlled, attention may be focused on underlying causative factors. (3) Symptomatic relief may enable the patient to function more effectively in his daily life while your work with the patient progresses.

Tablets TRIAVIL are available in four different combinations affording flexibility and individualized dosage adjustment. Since it is simpler to remember to take one tablet rather than several (particularly in multiple daily doses), your patients on TRIAVIL will be more likely to take proper doses of the medication.

TRIAVIL is contraindicated in CNS depression from drugs; in the presence of evidence of bone marrow depression; and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

MSD
MERCK SHARP & DOHME

For a brief summary of prescribing information, please turn to the following page.

when patients exhibit moderate to marked anxiety or agitation with symptoms of depression

TRIAVIL® **containing perphenazine and amitriptyline HCl**

a tranquilizer-antidepressant

for highly effective relief of depression with moderate anxiety

TRIAVIL®

containing perphenazine and amitriptyline HCl a tranquilizer-antidepressant

Available:

TRIAVIL® 2-25: Each tablet contains 2 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 2-10: Each tablet contains 2 mg perphenazine and 10 mg amitriptyline HCl

TRIAVIL® 4-25: Each tablet contains 4 mg perphenazine and 25 mg amitriptyline HCl

TRIAVIL® 4-10: Each tablet contains 4 mg perphenazine and 10 mg amitriptyline HCl

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Do not give concomitantly with MAOI drugs because hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. Allow minimum of 14 days between therapies, then initiate therapy with TRIAVIL cautiously, with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given with guanethidine or similarly acting compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, particularly in high doses, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. Caution patients performing hazardous tasks, such as operating machinery or driving motor vehicles, that drug may impair mental and/or physical abilities. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Side effects may be any of those reported with phenothiazine drugs: extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased or another drug substituted, the syndrome may be masked. It has been suggested that fine vermicular movements of the tongue may be an early sign of the syndrome, and that the full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; hypnotic effects; pigmentary retinopathy; corneal and lenticular pigmentation; occasional lassitude, muscle weakness, mild insomnia. Other adverse reactions reported with various phenothiazine compounds include blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); liver damage (jaundice, biliary stasis); grand mal convulsions; cerebral edema; polyphagia; photophobia; skin pigmentation; and failure of ejaculation.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness; weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; jaundice; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

I CLI ICALLY SIG IFICA T DEPRESSIVE NEUROSIS...

For Brief Summary, please see following page.

SANDOZ
75-379

RESULTS OFTEN SEEN IN A WEEK

Because the somatic and psychic complaints that accompany depressive neurosis can interfere with the treatment of the underlying psychopathology—rapid relief of these symptoms is often crucial to therapy.

In 14 double-blind studies of four weeks duration, 339 patients with depressive neurosis received Mellaril. In these studies, 55% of the overall improvement was observed by the end of the first week, and a total of 293 patients (86%) improved during the four weeks.*

Mellaril usually does not cause euphoria or undue sedation and is nonaddicting. Patients, therefore, generally remain alert and better able to respond to therapy. (The physician should, however, caution patients against participating in activities which require complete mental alertness, e.g., driving.)

*Data on file at Sandoz Pharmaceuticals.

MELLARIL®
(THIORIDAZINE)

TABLETS: 25 mg and 50 mg thioridazine HCl, U.S.P.

for the short-term treatment of moderate to marked depression with variable degrees of anxiety in patients with depressive neurosis

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg. should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling. The following reactions have occurred with phenothiazines and should be considered: *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient. In adults with depressive neurosis the usual starting dosage is 25 mg t.i.d. and the dosage ranges from 10 mg b.i.d. to q.i.d. in milder cases to 50 mg t.i.d. or q.i.d. for more severely disturbed patients; the total daily dose ranges from 20 mg to a maximum of 200 mg.

THE AMERICAN JOURNAL OF PSYCHIATRY

Women in Psychiatry: A Review

BY NANCY A. ROESKE, M.D.

Throughout the world, psychiatry is in a period of accelerated transition. In each nation the role of women in psychiatry, and the role of psychiatry in the lives of women, reflect one aspect of the development of egalitarianism. Women psychiatrists have perennially been confronted with conflicts between their professional and private life responsibilities. Internationally, the external and internal factors that prohibit or limit women's personal development and vocational participation are being scrutinized. American psychiatry is proving to be a pioneer among medical specialties in this area.

THE UNITED NATIONS designated 1975 as International Women's Year. This action called attention to the universal right of women to have an equal opportunity for self-development and self-expression. It has prompted many articles reviewing the current involvement of women in their country's educational, vocational, social, and political life (1, 2). As might be expected, there is evidence that cultural attitudes are changing slowly, even in countries where laws make women the equal of men. In addition to cultural attitudes, other key factors affecting the role of women include 1) each nation's decisions about its economic requirements, and 2) the health care needs of its people.

Thus the presence and role of women psychiatrists reflect the complex interaction of historical, cultural, religious, economic, educational, political, and legal factors in each country. The role of women psychiatrists must be understood within the context of the role of psychiatry, the role of women physicians, and the evolving role of all women within each nation.

Dr. Roeske is Professor and Director of Undergraduate Curriculum, Department of Psychiatry, Indiana University School of Medicine, 1100 West Michigan St., Indianapolis, Ind. 46202.

The author wishes to acknowledge the invaluable assistance of the staffs of the Division of Mental Health and the Library of the World Health Organization, Geneva; Ms. Ann Van Camp, Librarian, Indiana University School of Medicine; and Ms. Pauline Neff, secretary to Dr. Roeske.

VARYING CONCEPTS OF PSYCHIATRY AND WOMEN PSYCHIATRISTS

The number and role of women physicians, and the teaching and practice of psychiatry, vary remarkably throughout the world (3, 4). The German Federal Republic, Poland, the Union of Soviet Socialist Republics, and the United States of America report the largest number of women physicians (see table 1). Data are currently unavailable from China. Viewed in terms of percentages, however, in the 1960s the United States, Spain, and Japan were cited as having the lowest percentages of women physicians (United States, 6.8%; Spain, 9.1%; Japan, 8%) (5). Cultural attitudes antithetical to women in medicine were described as major deterrents. The percentages of women physicians in western European countries and other English-speaking countries, notably Canada and Australia, have been reported as varying between 15 and 30% (5).

The most significant reasons given for the higher percentages of European women seeking professional training include 1) the European tradition of family continuity in careers (so that a daughter may be encouraged to enter her father's profession), and 2) the loss of men during World War II (5, 6). This latter factor has been particularly important in the United Kingdom, Germany, Poland, Finland, Czechoslovakia, Austria, Yugoslavia, and the U.S.S.R. (3). In Russia, the following factors have been described as contributing to a woman's choice of medicine as a career: a general necessity for self-support because of the acute shortage of husbands due to wars and purges; a necessity for lifelong work, even if one is married, because of the low family income; and limited options for women who want to rise out of the lowest working class, since men are given preference in the nonmedical sciences and in engineering. Yet despite the large number of women physicians in the Soviet Union, less than 5% of them achieve high-level medical posts in administration, academia, and research (7, 8).

The 1970 *World Health Statistics Annual* (3) gives a reliable but limited review of the worldwide distribu-

TABLE 1
Countries with Comparable Numbers of Women Physicians, 1970*

Psychiatrists	14,500	—	—

* Based on data from the World Health Organization (3).

tion of physicians by sex, according to their medical specialty. Although every country in the world was asked to submit data, only 69 complied. The variability of completeness of the data, the differences in training patterns, and the different concepts of a psychiatrist's identity and function all pose problems in making international comparisons of men and women psychiatrists.

For countries reporting similar numbers of women physicians, it is interesting to review the number of psychiatrists in general, and of women psychiatrists in particular (see table 1). Although it is not necessarily a reflection of the role and importance of psychiatry in medicine, psychiatrists are present in appreciable numbers in only the United States and the U.S.S.R. (3). The exceptionally large number of psychiatrists in the United States attests to the impact of pre- and post-World War II immigration. Although Russia reports fewer psychiatrists than the United States it may have more women psychiatrists, since three-fourths of all its physicians are women. (Statistics that would confirm this possibility are unavailable.)

Mental health specialists, including psychiatrists, are in very short supply in nearly all of the developing countries (3). It is understandable that the few practicing physicians in these countries are primarily involved in child and maternal health, general medicine, public health, parasitology, and virology. This is not to say that these countries are without mental illness; epidemiological studies of mental disorders have shown a similarity between morbidity rates for the more severe disorders in both developed and developing countries (the United States vs. many countries in Africa, for example) (9). Nonetheless, psychiatry is a seriously neglected subject in most medical schools in developing countries. If courses are offered at all, they consist mainly of presentations of hospitalized patients by part-time faculty (4). Mentally ill persons are usually treated by male village healers, who may work in collaboration with local physicians (9).

Because of the limited availability of medical training programs in developing nations, their psychiatrists are usually educated in the United States or Europe. Yet the cultural dissonance between the country where the psychiatrist is educated and the country where she or he practices presents problems of professional adaptation.

As might be anticipated, there are few women psychiatrists in the developing nations. This situation is due to the following factors: cultural attitudes toward higher education and professional occupations for women, social attitudes about women traveling and living alone for educational and professional reasons, the expense of an education abroad, and dual wife-husband career problems and family conflicts. Nonetheless, the foreign woman medical school graduate frequently comes to the United States and later plays an important role in American psychiatry. Forty percent of the women psychiatrists in the United States are foreign medical graduates (10); about 36% of the rest of the women physicians in the United States are also foreign medical graduates (11). In the past 5 years an appreciable number of these women have probably come from Asian countries (11), although specific data regarding country of origin are currently unavailable. These women are confronted with the problems of language, acculturation, and a less than adequate medical school education in psychiatry.

FACTORS INFLUENCING WOMEN'S PROFESSIONAL LIVES

When examined in the light of their effect on women in psychiatry, the statistical reports from the World Health Organization (3) can be viewed as a commentary on the impact of such factors as each nation's culture and its health care needs. Unfortunately, however, fewer than 40 studies in the English literature have made a detailed investigation of the factors influencing the professional lives of women physicians, including psychiatrists.

Still, the results of research in the United States (12–22), West Germany (23), England and Scotland (24–31), Canada (32–34), Australia (35), and New Zealand (36) indicate remarkable similarities in women physicians' experiences and personality characteristics. These similarities include family background, the effect of marriage and children on the woman's career, the effect of the availability of professional education and experience on the woman's career, the results of personality assessment tests, and the woman's self-perception. Hence, a fairly valid composite profile of women psychiatrists can be derived from these studies.

It should be kept in mind, however, that statistics are as much a point of view as they are a method; they are a way of asking questions and examining evidence. Therefore the reader should be aware of a number of methodological problems that become apparent upon detailed comparison of research projects. These in-

clude variations in the following areas: the size of populations; composition of populations (age, specialty training, and geographical location, including specific characteristics of educational institutions); focus of the study (longitudinal vs. cross-sectional); number of research topics; the questions concerning a given topic; and the types of tests used to assess personality characteristics. A final methodological problem is the frequent absence of a comparable group of men.

It is noteworthy that the vast majority of the studies of practicing women physicians have dealt with a population sample that was educated prior to 1965, although many of these projects have been published in the literature since 1970. Therefore there is a need for current research to clarify the factors that facilitate and impede a woman psychiatrist's career.

These studies demonstrate that a woman's choice of a medical specialty is not directly related to her degree of professional involvement (14, 15, 17, 22). Contrary to popular opinion, women do not seem to choose psychiatry in order to work full-time. Women with children are just as likely to work part-time in psychiatry as in any other field of medicine.

Composite Profile of the Woman Psychiatrist

The composite picture presented by studies of the practicing woman psychiatrist (12–36) is one of a highly self-reliant woman who seeks to balance the demands upon her private life with the available options for professional education and career. Women psychiatrists are more likely than nonphysician women to have been raised in an urban community family, where the father had a university education and was a professional person and the mother was educated beyond secondary school and worked during the psychiatrist's childhood. Both parents stimulated and supported their daughter's interest in higher education and a profession. The decision to become a physician was usually made before or during early adolescence. Women psychiatrists have usually had a high interest in biological sciences and a desire to help people. They are different from the majority of other university women in their persistence to achieve self-expression. Outstanding achievement in medical school and in specialty training is unrelated to later career patterns. Approximately 80% of women psychiatrists marry, and 50% of them marry physicians.

They have the same number of years of postgraduate training as men, although their training and/or professional practice is usually disrupted by child bearing, since flexible schedules in training programs and jobs in conjunction with day-care centers are rarely available. Women psychiatrists are more likely to work part-time or not at all, depending upon the number and ages of their children. (The amount of time for a career decreases rapidly when there are 3 or more children and/or the children are less than 5 years old.) Women are more likely than men to work in institutional settings with fixed employment hours, and on the average, married women have a more varied practice pattern (full-time, part-time, or not at all) than men do. Overall, women practice 30% fewer hours than men, although single women's professional involvement (hours and number of patients) is similar to that of their male counterparts. Approximately 35% of women and 50% of men psychiatrists have specialty certification. Few women psychiatrists (2–3%) are found in each of the following areas: education, research, administration, or the overall policy-making components of psychiatry (10, 11).

Career Development

Thus, for most women psychiatrists, their career pattern is a resolution of the conflicts generated by such factors as 1) familial demands upon their time versus familial support and help, 2) the availability of child care, 3) the availability of a flexible time schedule in training and jobs, and 4) the opportunity for career development in areas of psychiatry where few women are currently involved.

In many ways geography can be another crucial factor in the career development of women psychiatrists. Being located in a densely populated state, such as California or New York, correlates with having a greater degree of choice in terms of variety of jobs, location of education, and husband's career location.

Few articles have explored women's thinking about these factors and their resolution of these conflicts. English researchers Lawrie and associates (25, 26), Flynn and Gardiner (27), Stanley and Last (28), Eskin (29), and Whitfield (31), motivated by the shortage of physicians and the "wastage of woman power," have found that in Great Britain the national health care system limits a woman's career development since promotions are based on the amount of time spent in a career. High taxation, the unavailability and/or high cost of domestic help, geographical distance from educational institutions, and the lack of child care facilities are other factors limiting a woman's professional commitment. Therefore 25–30% of English women physicians state that they wish to work more than they are currently able to do, or that they have chosen to work in a specialty that was not their first choice. Finally, in Ashurst's recent report (37) on the women psychiatrists of southwest England, "lack of mobility" was cited as the major deterrent to career development of married women.

The Scottish researchers Ulyatt and Ulyatt (38, 39) have questioned whether it is only these external factors, realistic as they may be, which are the basis for career decisions. They stated that, while she is in medical school, a woman's anticipation that her marriage and family will take precedence over her career is inversely related to her working full-time. Such factors as her desire to be close to her family and her fear of damaging her children by absence are also inversely related to full-time employment.

Another study of factors influencing a woman's professional involvement was conducted by Heslop and associates (36) in New Zealand. More than half of the

married women with children, whether they worked full-time or part-time, chose the specialty or job that fitted in with their domestic arrangements and their husband's career decisions. For the women who did not work because of children, their loss of confidence and feeling of professional inadequacy were clearly regarded as major difficulties in resuming work. The women explained their absence from the areas of administration and education as being due to lack of interest, limitations of available time, and the unlikelihood of appointment in a predominantly male profession.

Career Conflicts

Women's perception of men's acceptance and support of their careers was experimentally studied by Horner and Walsh (40). In their study of women and men medical students they found that the conflicts between achievement in medical school and acceptance by male peers resulted in women lowering their level of academic achievement. Later, as physicians, women may think they should be more passive than men think is necessary. Steinmann and associates (41, 42) found that eager, ambitious women physicians often thought that men's ideal woman was a "very passive one." On the other hand, the men physicians' ideal woman was in fact active, outgoing, and oriented toward self-realization. In addition, Shapiro (43) explored the feelings of physician-mother psychiatry residents in a pioneer part-time program at New York Medical College (44), the choice of which reflects the women's desire for a lifestyle that incorporates their interests in both family and profession. In the examples given of dual career development conflicts, the husbands were more tolerant of separation for a period of time than the women had anticipated.

Of all the possible solutions to the pressures and demands made on the life of the woman physician, the most negative and self-destructive answer to conflicts in public and private life is suicide. The suicide rate of women physicians in the United States (33.6 per 100,000) is three to four times higher than that expected for women over 25 years old (45, 46). The suicide rate of women physicians does not differ statistically from that of men doctors. However, women physicians differ from other women and from men physicians in their prime age range for suicide. Almost half of the suicides by women physicians occur before age 40, and approximately three-fourths occur before age 50. In comparison, half of the suicides by men physicians occur before age 50. The small sample size of the populations in the two studies cited (17 women in the first study and 41 in the second) does not lend itself to valid statistical analysis of other factors, including choice of specialty and marital status. There is an indication, however, that single women in residency training are the most vulnerable group.

Comment

Our present understanding of women psychiatrists is based upon research of the 1960s. The 1970s have seen an international burgeoning of articles about women in both the popular and scientific literature. Women and men writers have questioned and reviewed the biological, cultural, economic, legal, philosophical, and religious sanctions that, in effect, degrade women. Whether or not this present awareness can modify women's decisions about their careers will also depend upon changes in education, organizations, and institutions. The extent to which changes have occurred, and their effect upon women psychiatrists' careers, have yet to be reported in the literature from other countries.

AMERICAN WOMEN IN PSYCHIATRY—1975

For the past 50 years psychiatry has been the second most frequently chosen specialty by women (pediatrics is the first) (11, 14, 15, 47). Therefore, because of the number of women psychiatrists and the humanistic concerns of the profession, it is not surprising that the American Psychiatric Association appointed a task force on women in 1972. Among the medical specialties, psychiatry is a pioneer in this area. However, when considered within a wider educational and sociological context, the changes in the field of psychiatry are similar to the changes that have occurred in the organization of other branches of higher education (notably in the areas of sociology and psychology) (48). In each instance, a relatively small group of women has become involved in investigation and research. The results of this involvement include greater activity by other women in the profession and recommendations for organizational changes within the professional associations.

Following a caucus at the 1972 APA annual meeting, the Task Force on Women was formed to examine both the role of women in psychiatry and the effect of psychiatry in the lives of women (22, 49–52). At the 1973 and 1974 annual meetings there was a substantial increase in the number of papers (4% to 15%) presented by women, and spouses were invited to attend the professional meetings and were provided with a pamphlet of program excerpts. In 1975, for the first time, child care was provided at the annual meeting.

A number of organizational changes were simultaneously taking place. The number of women in the legislative components of the organization was increased to equal the 12% of women members in the Association. Dr. Rebecca Solomon was the first woman to be appointed to the Editorial Board of the *American Journal of Psychiatry* (1973). Dr. Jeanne Spurlock was the first woman to be appointed as a Deputy Medical Director of the Association (1974). In 1974 the Board of Trustees accepted the recommendation of the APA Task Force on Women for a committee on women. The major purposes of the Committee on Women are as follows:

1. To define and recommend action to meet the mental health needs of women by reassessing the current

theory and practice of psychiatry in terms of its congruence with the realities of women's lives.

2. To promote women psychiatrists' involvement in academics, research, administration, and professional organizations and to develop methods for increasing their participation and leadership.

3. To review and stimulate research and the development of theories necessary to implement the first two purposes.

4. To provide support systems for women colleagues.

The significance of this anticipatory action will be revealed over time. However, the charges given to the committee reflect the awareness of the task force that never before in American history have so many women sought higher education and professional careers. The exigency of the situation is supported by two facts: the rapid rise in the number of women entering medical school and the limited knowledge about women psychiatrists as teachers, researchers, administrators, and therapists.

In the 1975–1976 first-year medical school classes nationwide, women comprised 23.8% of the enrollment. The total enrollment of women medical students was 11,417 or 20.5% (53). The proportion of women psychiatry residents is also rising gradually, from 19.8% in 1972 to 22.4% in 1974 (10). In 1974 there were 878 women residents (421 U.S. and Canadian graduates and 457 foreign graduates) in general psychiatry and 131 women (61 U.S. and Canadian graduates and 70 foreign graduates) in child psychiatry (54, p. 1365).

The majority of women psychiatrists are educated and work in the following 7 states: New York, California, Massachusetts, Pennsylvania, Illinois, Maryland, and New Jersey. (New York with 723 and California with 301 women psychiatrists have one-third of all women psychiatrists in the country.) Montana, North Dakota, South Dakota, Nevada, Wyoming, and Idaho have 4 or fewer women psychiatrists. This pattern is similar to the geographical distribution of women in other specialties (55).

Gender Identity

While there are numerous raw statistics about women medical students and the professional activities of women psychiatrists (see tables 2 and 3), detailed descriptive data are meager. (There may be slight variations in data for a given year depending upon sources used.) The meaning of being a woman to the woman resident and her teachers, to the woman therapist and her patients, to the woman teacher and her students, to the woman researcher and her teachers and colleagues, and to the woman administrator has received scant attention. The few published articles are valuable personal accounts (50, 51, 58–62).

In general, there appears to be repeated denial that a person's sexual identity modifies interpersonal relationships. Women psychiatrists in residency training have noted that they and their male and female supervisors deny that being a woman influences the supervisory experience or the woman's role with her patients (22, 49–52). Yet in the face of all this denial, the woman psychiatrist can find herself expected to fulfill stereotypical feminine roles with and for men colleagues (58, 59). In addition, women psychiatrists may be objects of envy, anger, competition, and identification by nonpsychiatrist professional women, women patients, and nonprofessional women.

As therapists, women psychiatrists may be particularly helpful to the severely disturbed patient who had a distorted mother-child relationship, and to the hysterical woman, who cannot manipulate another woman (60, 63). Many women now seek out a woman therapist in an attempt to clarify their role as women and to remove themselves from the traditional "man in power-woman subservient" model. In therapy, these women focus on their ambivalence about the nurturing capabilities of the therapist, their ingrained belief that women are basically second-rate persons, and their ingrained socially conditioned attitude that women are only rivals for men and are therefore not to be trusted.

It may also be advantageous for some men patients to be seen initially or throughout therapy by a woman psychiatrist. For example, a man may be afraid of

TABLE 2
Distribution of U.S. Women Psychiatrists by Professional Activity and Specialty, 1972*

Professional Activity	General Psychiatry	Child Psychiatry	Psychoanalysis
Office-based practice	1,349	413	38

** This category includes other U.S. ethnic groups and nonwhite foreign graduates.

seeing a man psychiatrist because of a latent wish for passive homosexual surrender. The patient's anxiety may be greatly diminished if he is seen by a woman therapist (64).

Feelings and attitudes about sexuality, nurturance, power, fear of abandonment, competition, and hostility of patients, other psychiatrists, and other professional colleagues are intensified when the woman psychiatrist is pregnant (22, 49–52, 61, 62). Everyone, including the woman herself, is confronted with the realities, as well as the fantasies, of the woman psychiatrist as a person. The combined effect of psychophysiological vulnerability and career-family conflict can complicate the woman therapist's interpersonal relationships with her husband, patients, and colleagues. On the other hand, working through these conflicts can be a remarkably productive experience for therapist, patients, colleagues, and supervisors.

Choice of Professional Activity

The woman who chooses to direct her professional interests toward academia faces numerous problems beyond those confronted by the clinician. Of primary importance is the question of whether women have opportunities for academic careers. This question can be answered statistically. In 1975 there were 269 women psychiatrists and 2,417 men psychiatrists on the faculties in U.S. medical schools. Women comprised 10% of all psychiatry faculty and 9.9% of all medical school faculty (56). Few of these women are found at the higher levels of academia and research. Traditionally, the development of an academician and researcher has involved a continuity of career including research, presentations at meetings, and publications. The demands of family at the time of transition from student to faculty member represent a critical factor for career development along these lines; family pressures often act as significant deterrents.

To perhaps an even greater extent, the career problems of the woman academician and researcher carry over to the careers of women psychiatrists in administration. There is a social stereotypical factor that may be of great significance to the woman administrator. A woman who wishes to be a capable leader must refute the stereotype of being weak, emotionally labile, illogical, and unintelligent, or of being powerful and castrating. If a woman administrator is not authoritative she may be ignored as a passive woman; if she is too authoritative, she may be viewed as a destructive woman. The conflict between nonthreatening passive femininity and the demand for competence, which involves competitiveness, is very difficult for a woman to resolve; it is a constant issue for her. All of these factors may be related to the fact that in 1975 there was no woman who was chairperson of a department of psychiatry.

Role in Psychiatric Training Programs

Until 1974 there had been no reports about the role of women in psychiatric training programs. In that year the APA Task Force on Women conducted a survey of 300 such programs (65). Preliminary returns (N=167) yielded the following data: few programs actively recruited either men or women, although there was more of a tendency to actively recruit men; approximately 1 out of 5 programs reported different interviewing procedures for men and women applicants (such as asking women about their marital or family status or plans). Half of the programs offered part-time or flexible schedules for residents; child care facilities were available at only 1 out of 10 programs.

Seminar work on the psychology and sociology of women, sex roles, and gender identity was given by 1 out of 8 programs, usually on an optional basis. Few of the programs actively recruited women faculty members, and half of the programs used personal contact only in recruiting faculty members; half of the programs considered the sex of the teacher nonrelevant; more than one-third of the programs had no course hours taught by women faculty; and 10% of the supervisory hours were conducted by women. Almost all of the training programs reported that there had been no formal discussion about the status of women psychiatrists, the status of other women employees in the department, or issues regarding the treatment of women patients. Recent data (1974) revealed that 16 men and 33 women held part-time residency appointments (54). Although the reasons for this choice were not stated, the information supports the need for flexibility in residency programs for men and women.

In summary, all of the information to date about women and psychiatry supports the conviction that psychiatric residency training programs should be evaluated and possibly altered in order to increase women's competence and contribution to their field. As is so often the case, our actual behavior often differs markedly from our professed desires. Yet the increased number of women applying to residency programs will continue to stimulate changes in American psychiatric training programs.

Personal Characteristics

The fact that women's personality characteristics are particularly suitable for the role of psychiatrist has been noted by men psychiatrists for many years (66–68). Drs. Daniel Blain (67) and Karl Menninger (68) have written that women's attributes of intuitiveness, empathy, patience, and verbal skill are needed in psychiatry. These comments have been supported by research on the personal attributes of women and men medical students (13, 19, 34, 69) and by Lopate's book *Women in Medicine* (47), which is an excellent compilation of all the research in the United States prior to the mid-1960s. The Medical College Aptitude Test has been one of the standard criteria for admission to medical school. Women have usually scored higher than men in verbal ability (a measure of vocabulary strength and ability to perceive verbal relationships) and general knowledge (a measure of factual knowledge in nonscientific fields including art, eco-

nomics, geography, government, history, literature, music, philosophy, and psychology) (47).

Researchers in the United States (12, 13, 19, 70), Canada (34), and Scotland (69) have compared the personality characteristics of women and men medical students. In spite of the variety of assessment methods used, the studies consistently reported differences between women and men medical students and between women medical students and other university women. Women medical students were reported to be more thoughtful and subdued than their male counterparts, yet more apt to be anxious (a factor that correlated with superior academic performance); they were more likely to view themselves as totally committed to their goals and relatively content with them. They were more willing to express their feelings and to admit weaknesses and were less likely than men to endorse the extremes of dominant and aggressive behavior. They were more alert to moral and ethical issues and less apt to convey their own ethical attitudes and values to patients. They had a greater need for personal involvement with patients, although not to the extent of creating an unprofessional approach. Finally, the women medical students valued independence and individuality to a greater degree than men colleagues or other university women.

CONCLUSIONS

Throughout the world, psychiatry is in a period of accelerated transition. In each nation the role of women in psychiatry, and the role of psychiatry in the lives of women, reflect one aspect of the development of egalitarianism. Food limitations, population control, and economic demands linked with laws governing the equality of human rights are powerful reinforcers for increasing the possibility of self-expression by all women. Internationally, the external and internal factors that prohibit or limit women's personal development and vocational participation are being scrutinized. American psychiatry is proving to be a pioneer among medical specialties in this area.

Lithium in the Treatment of Depression

BY JOE MENDELS, M.D.

The author reviews the studies of lithium as an antidepressant, evaluates the evidence that there might be a specific subgroup of patients for whom it is effective, and reports a study he and his associates conducted that found lithium to be effective for 13 of 21 depressed patients. He concludes that there is convincing, although not conclusive, evidence for an antidepressant effect of lithium and that only by identifying the subgroup of patients for whom it is effective can the continuing uncertainty surrounding lithium's role in affective disorder be resolved. He also calls for a reevaluation of the relationship between mania and depression.

IT HAS BEEN about 8 years since my colleagues and I started to examine the potential antidepressant effect of lithium carbonate. Although the use of lithium for the treatment of depression remains controversial, I think that there is today a reasonable body of evidence supporting the view that it is an effective antidepressant in a subgroup of patients. The precise definition of this group of patients and the determination of whether the lithium by itself is a sufficient antidepressant for all of them remain unresolved.

Given the history of false claims for the use of lithium salts in medicine—including the nineteenth-century claims for its role in the treatment of epilepsy, insomnia, gout, and as a general tonic or sedative—it is not surprising that new claims for its therapeutic usefulness should be treated with reservation, if not outright suspicion.

The claim for an antimanic effect for lithium was first made in 1949 by Cade (1). It took over 20 years for this idea to gain widespread acceptance in North America. The subsequent observation that lithium exerts a prophylactic effect in patients with recurrent affective disorder has achieved acceptance, at least insofar as manic-depressive or bipolar depressive disorder is concerned, in about 10 years—a substantial reduction in lag time. It remains to be seen how long it will take for lithium's role as an antidepressant to be clarified.

I have reviewed the available reports dealing with the antidepressant effect of lithium in detail elsewhere (2, 3) and need only to summarize them here. I will confine myself primarily to the controlled studies and mention the uncontrolled reports only in passing.

I will then briefly evaluate the evidence that there may be a specific subgroup of patients for whom lithium is a useful antidepressant. It is only by the identification of this subgroup of patients that we can expect to resolve the continuing uncertainty surrounding this question. The definition of such a group of patients obviously has important practical as well as theoretical implications.

Finally, I will discuss the theoretical implications of the findings that lithium has a specific antimanic effect and that it may also be useful as an antidepressant. Clearly, this calls for some reevaluation of our conceptualization of the relationship between depression and mania.

REPORTS OF LITHIUM AS AN ANTIDEPRESSANT

Table 1 summarizes 9 uncontrolled studies (1, 4–11). Although no conclusions should be reached on the basis of these reports, it is of interest to note that 6 of the 9 studies listed in this table claimed some antidepressant effects for lithium, while 2 of the 3 negative reports involved early studies with small numbers of patients for which little information is available.

Including the research reported in this paper, there are 10 controlled studies from 8 centers (5, 12–19) in which the effect of lithium alone was tested. Three of these studies (5, 12, 13) claimed no significant antidepressant effect for lithium, while 7 (14–19 and the study reported below) reported a clear-cut effect. These 10 studies are summarized in table 2.

Negative Studies

Of the 3 studies that concluded that lithium did not have any significant antidepressant effect, 1 is an unpublished study cited in a review of lithium (5) and is therefore difficult to evaluate. The 2 more recent studies concluded that lithium has only a "mild antidepressant effect" (12) or was not statistically significantly

Presented at the 128th annual meeting of the American Psychiatric Association, Anaheim, Calif., May 5–9, 1975.

Dr. Mendels is Professor of Psychiatry and Chief, Depression Research Unit, University of Pennsylvania School of Medicine and Veterans Administration Hospital, Philadelphia, Pa. Address reprint requests to him at the Veterans Administration Hospital (151E), Philadelphia, Pa. 19104.

This research was supported in part by Alcohol, Drug Abuse, and Mental Health Administration grant MH-25433 from the National Institute of Mental Health and by research funds from the Veterans Administration.

TABLE 1
Summary of Uncontrolled Studies of Lithium as an Antidepressant

Study	Number of Patients	Patients' Description	Comment
Cade (1)	3	Chronic depressive psychosis	No effect
Noack and Trautner (4)	—	—	No effect
Vojtechovsky*	14	Depression; ECT failure	8 responded
Andreani and associates (6)	24	Severe depression	10 improved
Dyson and Mendels (7)	31	Heterogeneous group of depressed patients	19 improved, especially those with bipolar/ cyclothymic disorder
Van der Velde (8)	—	Mixed affective disorder (bipolar and unipolar); relapsing bipolar disorder	No effect after 14 days' treatment
Noyes and associates (9)	5	Bipolar affective disorder (N=3); unipolar affective disorder (N=2)	4 improved; 2 relapsed with placebo
Náhunek and associates (10)	98	Endogenous or involutional depression	55 improved
Bennie (11)	14	Depression; no response to ECT and/or tricyclics	14 improved

* Vojtechovsky's work, "Zkusenosti s lecbou solemi lithia," was cited by Schou (5).

superior to placebo (13). Examination of these conclusions shows that there *was* a clear-cut improvement in the depressed patients treated with lithium. The group of patients studied by Fieve and associates (12) appears to have consisted primarily of bipolar patients, but there is no information available to allow for this distinction to be made in the group studied by Stokes and associates (13). Furthermore, insufficient information is provided to allow us to determine if the patients received an adequate dose of lithium (with adequate plasma concentrations) for a sufficiently long period of time so that we could be reasonably certain that they received an adequate therapeutic trial. The patients studied by Stokes and associates (13) appear to have received lithium in increasing doses for only 10 days, probably too short a time to allow for an adequate evaluation.

It is possible that the rating scales used by these investigators may not have been sufficiently sensitive. For example, Stokes and associates (13) divided their patients into three categories: improved, worsened, and no change. They did not provide details of the changes in their patients. Thus the clear trend toward improvement in their patients may have been partially obscured by their rating procedures. Their patients did show a statistically significant reduction in depressive symptoms during the 10 days of lithium administration in comparison with depression ratings on the day before the institution of lithium treatment ($p<.005$ by one-tailed Wilcoxon t test).

Fieve and associates (12) reported that there was no significant difference in the responses to lithium and imipramine in their patients after 2 weeks of treatment. It was after this that they found a superior response to imipramine. However, it is important to note that there was a *continuing* improvement in the patients treated with lithium throughout the entire study period.

It seems possible that the relatively negative conclusions regarding the potential antidepressant effect of lithium carbonate reached by these authors may be subject to reinterpretation. It is clear that there was improvement in the patients who were treated with lithium alone; the authors' conclusions may have been affected by any one of several experimental variables. Thus I think that it would be reasonable to conclude that their findings are equivocal rather than negative.

Report of a Recent Study

I would like to briefly summarize our most recent study in this area; this research has not been previously reported.

My associates and I conducted a placebo-substitution controlled study of lithium carbonate in a group of 21 moderately or severely depressed hospitalized patients (their mean Hamilton score [20] at the time of entry into the study was 28.1). Thirteen of the patients were bipolar, and 8 were unipolar. All of the patients received placebo for 7 to 15 days after their admission to the hospital and after the initial medical and psychiatric evaluation. They were then given lithium carbonate in increasing doses to a point of either clinical improvement, a plasma concentration of 1.5 mEq/L, or the development of troublesome toxicity. The optimal or maximal dose of lithium for each patient was maintained for 21 days. This was followed by 7 to 22 days of placebo substitution; neither the patient nor the medical or nursing staff involved in patient management and evaluation were aware of the times when changes were made from placebo to lithium. It is, of course, possible that the patients and/or the staff became aware of the substitution because of subjective or objective effects from the lithium, e.g., slight tremor.

The primary criterion for response was that the patient have sufficient relief of symptoms with lithium that he did not require any other form of active treatment and appeared able to return to his premorbid occupation. Using this criterion plus changes in several rating scale scores—the Hamilton (20), Beck (21), and Bunney-Hamburg (22) scales—13 of the 21 patients improved (9 bipolar and 4 unipolar). Of these 13 patients,

TABLE 2
Summary of Controlled Studies of Lithium as an Antidepressant

Item	Number of Patients	Patients' Description	Research Design	Comment
Studies that found little or no antidepressant effect				
Hansen and associates*	12	Severe endogenous depression	Crossover with placebo	Several patients improved with lithium; only 1 relapsed with placebo
Fieve and associates (12)	29	Bipolar affective disorder	Comparison with imipramine	Imipramine's effect superior to lithium's "mild antidepressant effect"
Stokes and associates (13)	18**	Bipolar affective disorder	Comparison with placebo	Trend toward improvement with lithium, but not significantly superior to placebo after 10 days' treatment
Studies that found significant antidepressant effect				
Goodwin and associates (14, 15)	52	Mixed affective disorder (bipolar and unipolar)	Placebo substitution	15 complete and 21 partial remissions, especially among bipolar patients
Mendels and associates (16)	24	Mixed affective disorder (bipolar and unipolar)	Control group given desimipramine	Lithium as effective as desimipramine
Noyes and associates (17)	22	Mixed affective disorder (bipolar and unipolar)	Placebo substitution	13 responses to lithium (6 of 6 bipolar and 7 of 16 unipolar patients); 9 relapses with placebo
Johnson (18)	10	Endogenous depression	Placebo substitution	5 "marked" improvements
Baron and associates (19)	23	Primary affective disorder	Placebo substitution	5 unequivocal and 5 equivocal responses, especially among bipolar patients
Mendels***	21	Primary affective disorder	Placebo substitution	13 unequivocal improvements; 7 relapses with placebo, especially among bipolar patients

* Unpublished study cited by Schou (5).
** These 18 patients had 31 episodes of affective illness.
*** Reported in this paper.

7 relapsed with subsequent placebo substitution (6 bipolar and 1 unipolar).

Positive Studies

The reports that found that lithium has a significant antidepressant effect are also summarized in table 2. In all, 152 hospitalized patients with moderate or severe depression were included in these 7 controlled studies (14–19 and the study reported above). In all of these studies except 1 (16), the antidepressant effect of lithium was evaluated by placebo substitution. The patients received placebo before and/or after lithium. Most of these studies required that the patient improve with lithium and then relapse with placebo before a determination of unequivocal response was made. In all of the studies a substantial number of patients showed an unequivocal response, and a number of patients showed an equivocal response, i.e., they improved with lithium but did not relapse with placebo.

It should be noted that patients designated as equivocal responders were not necessarily placebo responders. Failure to relapse with placebo substitution, while suggestive, does not in itself mean that the initial response was independent of the pharmacological action of lithium. Lithium *may* have set in motion a train of events that led to the resolution of the illness so that the patient was indeed "cured" at the time of placebo substitution.

Examination of the results of these studies suggests that there is a clear trend for patients with a diagnosis of bipolar or manic-depressive illness to respond to lithium more frequently than patients diagnosed as having recurrent unipolar depression. However, it is also clear that many patients with a diagnosis of unipolar depressive illness respond to treatment with lithium carbonate and that not all bipolar patients respond to this treatment.

There is no one-to-one correlation between the diagnosis of bipolar illness and the antidepressant effect of lithium carbonate; other variables are presumably of importance here. For example, it is known that some patients diagnosed as unipolar may have manic episodes in the future. Thus, even among patients who have had three separate depressive episodes and have

never been manic and are therefore diagnosed as unipolar, 14% will have a manic episode at some time in the future (23) and will have to be rediagnosed as bipolar depressive.

Another possibility is that some unipolar patients may have a positive family history of bipolar illness and may therefore have the genetic endowment for bipolar illness. These patients may best be regarded as pseudo-unipolar depressive, in that they may have the biological characteristics of bipolar illness with a clinical history of unipolar illness.

The fact that not all bipolar depressive patients are lithium responsive is, of course, in agreement with the well-established findings that not all manic patients are lithium responsive and that lithium is not an effective prophylactic agent for all bipolar patients. Similarly, bipolar patients have not been shown to be a homogeneous group in any biochemical or electrophysiological study to date. This clinical syndrome may be biochemically and therapeutically heterogeneous.

Given the limitations and imperfections of our nosological systems, it may be pragmatic to simply refer to a lithium-responsive affective disorder rather than to try to force an artificial or premature fit between therapeutic response and clinical history. Perhaps the systematic study of lithium-responsive patients will eventually reveal some consistent and specific genetic and biological characteristics of this group, allowing them to be separated from the rest of the heterogeneous group of patients with affective disorders. Some preliminary attempts at this are noted below.

COMBINATION LITHIUM THERAPY

Table 3 summarizes 4 reports (24–27) that claimed that lithium exerts a synergistic effect when combined with a tricyclic antidepressant, a monoamine oxidase (MAO) inhibitor, or ECT. Three of these studies (24–26) were uncontrolled. However, they are worth noting because the authors referred to a number of patients who had previously shown a poor response to conventional antidepressant therapy. These observations, together with that of Lingjaerde and associates (27), who reported that lithium plus tricyclics were superior to tricyclics alone in a controlled study, provide provocative but inconclusive grounds to consider combination treatments for treatment-resistant patients. Clearly, there is a need for additional controlled studies of this treatment approach.

TABLE 3
Summary of Studies in Which Lithium Was Used in Combination with Other Antidepressants

Study	Comment
Hartigan (24)*	ECT plus lithium had synergistic effect
Zall and associates (25)*	Lithium plus MAO inhibitors or tricyclics had synergistic effect
Himmelhoch and associates (26)*	Severely depressed patients with hypersomnia improved with lithium plus tranylcypromine; no response to initial tricyclic treatment
Lingjaerde and associates (27)**	Lithium plus tricyclics had synergistic effect, especially when lithium plus imipramine-*N*-oxide used for endogenous depression

*Uncontrolled study.
**Controlled study.

CHARACTERISTIC FEATURES OF LITHIUM RESPONDERS

The following variables have been reported to be associated with the antidepressant effect of lithium: manic-depressive or bipolar illness (7, 15); family history of bipolar illness (7); "endogenous" symptom pattern (7); increased average evoked responses (19); "high" erythrocyte (RBC) lithium:plasma lithium ratio (28); "high" baseline plasma calcium:magnesium ratio (29); initial increase in plasma magnesium and calcium concentration with lithium treatment (29); and reduced accumulation of 5-hydroxyindoleacetic acid in lumbar spinal fluid (30).

It is important to note that all of these claims (with the possible exception of an association with bipolar illness) must be regarded as preliminary. However, it is of interest to note them in light of the possibility that there may be a specific subgroup of patients with a lithium-responsive disease. These claims may point to further studies that would help define the characteristics of this group of patients.

Of the symptomatic-historical features, the possible association between lithium response and bipolar illness has been discussed above. The reported association with an "endogenous" symptom pattern (7) is probably not specific for lithium-responsive patients because this symptom complex is relatively common and is probably associated with a response to other forms of treatment, including ECT (31) and tricyclic antidepressants (32).

The reported association between baseline plasma calcium:magnesium ratio as well as changes in plasma calcium and magnesium with the initiation of lithium treatment (29) is promising. If this idea is confirmed, it will provide a simple method for selecting patients for lithium treatment. However, only a preliminary report of this finding has appeared to date (29); it is therefore difficult to evaluate. Further investigation is clearly needed.

Frazer and I (28) reported that depressed patients who respond to treatment with lithium carbonate have a significantly higher RBC lithium:plasma lithium ratio than patients who do not respond but who receive a similar or even higher dose of lithium and achieve similar plasma lithium concentrations. There is evidence (33) that RBC lithium concentration has a significantly

higher correlation with brain lithium concentration than does plasma lithium. This suggests that greater accuracy in predicting brain lithium concentration is achieved from a knowledge of RBC lithium concentration than from knowing plasma lithium concentration.

For example, the predictability of brain lithium concentration from a knowledge of RBC levels ranges between 64% and 88%, contrasting with the predictability of brain lithium levels from a knowledge of plasma levels, which ranges from a low of 17% to a maximum of 62%. Thus, if one can extrapolate from our studies with rats (33), it is possible that patients with a higher RBC lithium concentration also have a higher central nervous system concentration of lithium than patients with low RBC lithium concentrations.

The higher RBC lithium:plasma lithium ratio in depressed patients who respond to treatment with lithium is probably a function of a proportionately higher RBC lithium concentration. This suggests that patients who respond to treatment with lithium carbonate may have some difference in cell membrane properties governing the entry of lithium into or out of the cell in comparison with patients who do not respond to treatment with lithium (34). This difference in RBC lithium: plasma lithium ratio is unlikely to be a function of variations in dietary sodium intake or plasma hormonal concentrations (34).

This phenomenon has several other interesting characteristics. The RBC lithium:plasma lithium ratio appears to stabilize fairly early in treatment and to show proportionately little change over time. Thus we rarely see "high ratio" patients become "low ratio" patients or vice versa. Frazer and I (34) also found that there is a statistically significant tendency for the RBC lithium: plasma lithium ratio to be higher in patients with a higher baseline RBC sodium concentration. Although lithium itself appears to cause some increase in RBC sodium concentration, this increase is more marked and more likely to occur in depressed patients who show a response to lithium treatment (34). No significant changes have been noted in potassium or magnesium concentrations.

In related studies (35, 36), my associates and I have found that RBC lithium concentration is at least in part under genetic control and that the factors which regulate the distribution of lithium are similar to those which regulate the sodium flux across the cell membrane. This suggests the possibility that there may be some genetically determined abnormality in sodium and lithium flux in patients who are lithium responsive and that lithium may serve as a useful marker in the identification of differences in cation transport in discrete groups of patients.

RELATIONSHIP BETWEEN DEPRESSION AND MANIA

In my opinion, the evidence for an antidepressant effect of lithium carbonate reviewed in this report is convincing if not yet conclusive. As noted earlier, the fact that a single drug, lithium, exerts both antidepressant and antimanic effects raises important questions about the relationship between depression and mania and suggests that they may not be two distinctly opposite conditions (37–39). The term "bipolar," implying two opposite states, may be a misnomer. Like many terms introduced into psychiatric nosology, it may carry greater implications than were originally intended. Indeed, there are a number of reports (2, 40–56) indicating that depressed and manic patients share important characteristics and are not simply opposite states. Although some of these remain controversial observations, they do indicate the importance of reevaluating the relationship between these two syndromes:

Symptoms. Many manic patients have concurrent symptoms of depression while in the manic state, including sadness, pessimism, guilt, self-doubt, crying, and suicidal preoccupation (40, 41).

Biological changes. Investigators have reported that some depressed and manic patients differ from control subjects in the following systems: reduced CSF concentration of 5-hydroxyindoleacetic acid (42, 43), reduced platelet MAO activity (44), reduced catechol-O-methyltransferase (COMT) activity (45), disrupted pattern of cortisol release into plasma (46), reduced transfer of Na_{22} from plasma to CSF (47), reduced CSF tryptophan concentration (48), increased amplitude response in cortical evoked potential (49), and similar alterations in sleep EEG in the two groups of patients (50).

Treatment response. Some manic and depressed patients may respond to the following: lithium carbonate (2, 51), ECT (52), tryptophan (53), imipramine (54, 55), and chlorpromazine (56).

It is also possible that lithium may exert its therapeutic action through different mechanisms in depression and mania (and perhaps through yet another mechanism when used prophylactically). Alternatively, lithium may act on the same systems by exerting a nonspecific homeostatic effect, bringing an elevated or a reduced activity back to some "normal" range. This would be a parsimonious explanation for its several, apparently different clinical effects.
